False Beliefs, Fig. 3 In the task of Scott et al. (2015), 17-month-olds saw three rattling-toy and three silent-toy familiarization trials; a different toy was used in each trial, and the six toys differed in color and pattern. In the rattling-toy trials, the owner entered with a toy on a tray; she shook the toy, which rattled, returned it to the tray, and then left (the toy rattled only when briskly shaken). In her absence, the thief shook the toy and then replaced it on the tray. When the owner returned, she stored the toy in a treasure box. In the silent-toy trials, the toy was silent, the thief did not shake it, and the owner discarded it in a trash can. In both test trials, the owner first brought in a rattling test toy that was visually identical to a silent toy she had previously discarded in the trash can; as before, she shook the toy and left. The thief then picked up the rattling test toy, looked into the trash can, and selected either the matching silent toy (matching trial) or a nonmatching silent toy (nonmatching trial). The thief placed the silent toy on the owner's tray, hid the rattling test toy in a pocket, and then paused

Familiarization trials

Rattling-toy trials

Silent-toy trials

Test trials

The two test trials began the same way and then continued as shown.

Non-matching trial

Matching trial

belief, and then they are prompted to perform some action for the agent; for children to succeed, their actions must be guided by an understanding of the agent's false belief. Positive results have been obtained with infants and toddlers using a variety of prompts, including helping the agent retrieve an object and selecting one of two objects

for the agent (Buttelmann et al. 2009, 2015; Southgate et al. 2010).

In the helping task of Buttelmann et al. (2009), for example, an experimenter first showed 18-month-olds how to lock and unlock two lidded boxes; the boxes were left unlocked. Next, a male agent entered the room, hid a toy in one of the

boxes, and then left. While he was gone, the experimenter moved the toy to the other box and locked both boxes. When the agent returned, he tried vainly to open the box where he had hidden his toy. When prompted to help him (“Go on, help him!”), most infants approached the box the agent had not acted on, suggesting that they understood he wanted his toy and falsely believed it was still in its original location (when the agent witnessed the toy’s transfer, infants inferred that he wanted to open the empty box, and they approached that box instead). Southgate et al. (2010) tested 17-month-olds with a similar task. An agent hid two distinct objects in two lidded boxes and then left; in her absence, an experimenter switched the objects. When the agent returned, she pointed to one of the boxes, said she wanted to play with the object in it, and asked the infants, “Can you get it for me?” Most infants approached the box the agent had not pointed to, suggesting that they understood she held a false belief about which object was in which box.

In addition to false beliefs about location, elicited-intervention tasks have been used to examine infants’ understanding of false beliefs about contents and identity. In a task on identity (Buttelmann et al. 2015), for example, 18-month-olds and an agent encountered a deceptive object, such as an object that appeared to be a toy duck, in each of four trials. The agent then left the room, and in her absence, infants learned the object’s true identity (e.g., the duck was in fact a brush). The deceptive object was then placed on a high shelf. When the agent returned and reached vainly for the deceptive object, infants were shown two test objects, one that matched the deceptive object’s appearance (e.g., a toy duck) and one that matched its true identity (e.g., a brush), and they were asked to give the agent what she wanted. Infants tended to choose the test object that matched the deceptive object’s appearance rather than the test object that matched its identity (this pattern reversed if the agent was present when the object’s true identity was revealed). Buttelmann et al. concluded that infants understood that the agent held a false belief about the identity of the deceptive object (e.g., she thought it was a toy duck) and used this belief to decide which test object to select for her.

Elicited-Prediction Tasks Revisited

How can we explain the discrepancy between the negative findings of elicited-prediction tasks and the positive findings of spontaneous-response and elicited-intervention tasks? At present, there are two main views on this question.

Two-system view

According to some researchers, two different psychological-reasoning systems underlie performance in elicited-prediction tasks, on the one hand, and in spontaneous-response and elicited-intervention tasks, on the other (Butterfill and Apperly 2013; Low and Watts 2013). In the two-system account of Butterfill and Apperly (2013), for example, the (conscious, non-automatic, slow, flexible) *late-developing* system emerges around 4 years of age as a result of linguistic, executive-function, and meta-representational advances; this advanced system is capable of representing false beliefs and other counterfactual states, and it makes possible correct responses in elicited-prediction tasks. The (unconscious, automatic, fast, inflexible) *early-developing* system is already present in infancy; although it cannot represent false beliefs per se, it can track simpler, belief-like “registrations” that are sufficient to allow success at spontaneous-response and elicited-intervention tasks. Upon encountering an object, an agent registers its location and properties; by tracking this registration – even if it becomes outdated in the agent’s absence – the early-developing system can predict the agent’s actions (e.g., an agent will search for her toy where she last registered it).

However, there are reasons to doubt that two systems with distinct neurological substrates and computational capacities underlie false-belief understanding in different tasks. First, neuroscientific investigations with adults indicate that elicited-prediction and spontaneous-response tasks engage anatomically similar regions within the temporal-parietal junction (Bardi et al. [in press](#)). Second, claims about the early-developing system’s signature limits (e.g., an inability to track false beliefs about identity or complex interactions among mental states) have been overturned

(Buttelmann et al. 2015; Scott and Baillargeon 2009; Scott et al. 2015). More generally, the sophistication of the false-belief understanding that has been revealed in many spontaneous-response and elicited-intervention tasks casts doubt on the view that infants and toddlers are capable of only a minimal form of false-belief understanding (for discussion, see Carruthers 2016; Scott et al. 2015).

One-system view

According to other researchers, a single psychological-reasoning system underlies performance in elicited-prediction, spontaneous-response, and elicited-intervention tasks (Baillargeon et al. 2016; Carruthers 2013; Leslie et al. 2004). In this view, young children's difficulties with elicited-prediction tasks stem from their heavy processing demands. Among these, two separate lines of research have highlighted the importance of executive-function and more specifically *inhibitory-control* demands. First, in their computational model of elicited-prediction tasks, Leslie and his colleagues proposed that an inhibitory process plays a key role in allowing children to express their false-belief understanding (Leslie et al. 2004). When children are asked the test question "Where will Sally look for her marble?", an inappropriate prepotent response focused on the marble's actual location is triggered (exactly why this is so is currently widely debated among developmental researchers). This prepotent response must then be inhibited for children to select an alternative response consistent with their representation of Sally's false belief. Because young children's inhibitory control is immature, however, they cannot effectively suppress this prepotent response and thus mistakenly point to the marble's current location.

Second, many correlational studies with 3- to 6-year-olds have reported a significant association between performance in elicited-prediction tasks and performance in tasks that tap inhibitory control and especially conflict inhibition, the ability to suppress a prepotent response while activating a conflicting response (e.g., saying "day" when shown a picture of the moon and saying "night" when shown a picture of the sun; Carlson and

Moses 2001; for a meta-analysis, see Devine and Hughes 2014). This association typically persists even when potentially confounding factors such as age and verbal ability are statistically controlled. These correlational findings are often taken to indicate that inhibitory-control advances are necessary for the *emergence* of false-belief understanding (Carlson and Moses 2001). In light of the positive results of spontaneous-response and elicited-intervention tasks, however, it seems likely that inhibitory-control advances contribute more to the *expression* of this understanding, as suggested by Leslie et al. (2004).

Predictions of the One-System View

If processing demands are the cause of early difficulties with elicited-prediction tasks, as the one-system view claims, then reducing these demands should enable young children to succeed at these tasks. In line with this prediction, many researchers found that when inhibitory-control demands were reduced by various means, 3.5- to 4-year-olds now succeeded at the tasks. However, children age 3 and younger performed only at chance. In an experiment by Setoh et al. (2016), for example, 2.5-year-old toddlers heard a low-inhibition story accompanied by a picture book: Emma found an apple in one of two containers, moved it to the other container, and then went outside to play with her ball; in her absence, her brother Ethan found the apple and took it away. Emma then returned to look for her apple. In the test trial, children were shown pictures of the two containers and were asked the test question, "Where will Emma look for her apple?" Because toddlers did not know the apple's actual location, the prepotent response triggered by the test question should have been weaker and hence easier to suppress. Nevertheless, toddlers performed only at chance.

The negative findings obtained with young children in low-inhibition elicited-prediction tasks were generally taken to constitute an important challenge for the one-system view (Devine and Hughes 2014; Wellman et al. 2001). Why was a reduction in inhibitory-control demands not sufficient to lead young children to express their false-belief understanding and perform above chance levels? Proponents of the two-system

view suggested that perhaps such a reduction could help only transitional children who were nearly 4 years of age and whose late-developing system was already beginning to emerge.

To address this challenge to the one-system view, Setoh et al. (2016) hypothesized that toddlers might have performed at chance in the low-inhibition Emma task described above because the *total amount of concurrent processing demands* in the tasks exceeded their limited information-processing resources, leading to random or confused responding. The task involved at least three processes: (a) *false-belief representation* (as the story unfolded, toddlers had to build and maintain a representation of Emma's false belief), (b) *response generation* (when asked the test question, children had to interpret it, hold it in mind, and generate a response), and (c) *inhibitory control* (toddlers had to inhibit the weak incorrect prepotent response triggered by the test question in order to tap their representation of Emma's false belief and generate the correct response). If toddlers failed because they were overwhelmed by the total amount of processing demands in the task, then they might succeed if this amount were lowered by *also* reducing response-generation demands via practice trials.

To test this prediction, Setoh et al. (2016) interspersed two practice trials among the story trials in the Emma task (Fig. 4). In one practice trial, children saw an apple and a banana and were asked, "Where is Emma's apple?"; in the other, they saw a ball and a Frisbee and were asked, "Where is Emma's ball?" In each case, toddlers were required to point to the matching picture. Note that these practice trials were not intended to support the false-belief-representation process: Pointing to the pictures of Emma's apple and ball was unlikely to help toddlers understand Emma's false belief about the apple's location. Rather, the practice trials were intended to support the response-generation process: They gave children practice interpreting a "where" question and producing a response by pointing to one of two pictures.

As predicted, toddlers now performed above chance in the test trial, pointing to the container

Emma falsely believed held her apple. In additional experiments, toddlers responded at chance when they received fewer than two practice trials or when they received two practice trials that did not match the test trial as closely (e.g., only one picture was shown in each practice trial), rendering them less effective at reducing response-generation demands. Finally, toddlers performed below chance when the practice trials were embedded in a high-inhibition false-belief story, thereby increasing inhibitory-control demands.

Based on these results, Setoh et al. (2016) concluded that there are at least two reasons why young children may fail at an elicited-prediction task. On the one hand, they may lack sufficient skill at one of the processes involved in the task; for example, they may lack sufficient inhibitory-control skill to suppress their own knowledge or resist "the pull of the real." On the other hand, they may be able to execute each process separately but lack sufficient information-processing resources to handle the total processing demands of the task.

Together, the results reported in this section thus provide strong support for the one-system view and for the claim that early failures at elicited-prediction tasks stem from limitations in young children's ability to cope with these tasks' processing demands, rather than limitations in their ability to understand false beliefs.

Conclusion

The results reviewed in this article suggest two broad conclusions. First, false-belief understanding emerges early in life, as evidenced by the converging demonstrations from spontaneous-response tasks, elicited-intervention tasks, and elicited-prediction tasks with reduced processing demands. Second, it is only by considering the full range of processing demands associated with each false-belief task that researchers can make sense of divergent findings within and across types of tasks.

These conclusions do not support the long-standing view of false-belief understanding as a major milestone in the development of

Story trial-1		“This is a story about a girl named Emma. Look! There’s Emma!”
Story trial-2		“Emma finds an apple in a bowl. in a bowl.”
First practice trial		<i>“Where is Emma’s apple?”</i>
Story trial-3		“Emma puts her apple in a box for later.”
Story trial-4		“Then she goes outside to play with a ball.”
Second practice trial		<i>“Where is Emma’s ball?”</i>
Story trial-5		“When Emma is gone, her brother Ethan finds the apple and takes it away.”
Story trial-6		“Emma is hungry. She comes in to look for her apple.”
Test trial		<i>“Where will Emma look for her apple?”</i>

False Beliefs, Fig. 4 In the task of Setoh et al. (2016), 2.5-year-olds faced a large picture book and heard a low-inhibition false-belief story. The story introduced Emma (trial 1), who found an apple in one of two containers on a table: a bowl covered with a towel and a lidded box (trial 2). Emma moved her apple to the other container (trial 3), and then she went outside to play with her ball (trial 4). In her absence, her brother Ethan found the apple

and took it away (trial 5). Emma then returned to look for her apple (trial 6). In the test trial, children saw pictures of the bowl and box and were asked, “Where will Emma look for her apple?” To reduce response-generation demands, two practice trials were interspersed among the story trials. In each practice trial, children saw two pictures and were asked a question that required them to point to one of them (i.e., “Where is Emma’s apple/ball?”)

psychological reasoning, which is not attained until the preschool years. Nevertheless, it may still be the case that humans' capacity for reasoning about false beliefs and other counterfactual mental states plays an important role in everyday social cognition. Many years ago, Leslie (1987) argued that pretend beliefs and false beliefs are fundamentally similar and that as infants have no difficulty understanding the former (e.g., in pretend play activities), performance factors must limit their ability to understand the latter. Building on the notion that pretense and false-belief understanding are closely related, Baillargeon et al. (2013) suggested that one critical function of counterfactual-state reasoning in daily life may be that it allows humans to understand and produce *social acting*, the well-intentioned social pretense that helps maintain positivity within social groups. Of course, counterfactual-state reasoning also makes possible strategic deception in competitive interactions, which infants also understand (Scott et al. 2015). According to the social-acting hypothesis, however, it is in the routine, everyday practice of social acting in cooperative interactions that humans make the most use of their capacity for holding in mind distinct representations of reality. White lies, tactful omissions, feigned interest, shows of loyalty where individuals publicly endorse opinions that diverge from their own – all of these require individuals to decouple what they privately think or feel from what they choose to communicate to others. As investigations of early social cognition are now expanding to include sociomoral reasoning, future research will be able to shed light more broadly on the various ways in which infants' abstract and early-emerging capacity for understanding false beliefs and other counterfactual states contributes to their social world.

False Negatives

Chi Lee and Joseph A. Camilleri

Westfield State University, Westfield, MA, USA

Error management theory was proposed to explain the evolution of cognitive biases, particularly errors in judgment (Haselton and Buss 2000). One type of error is known as a false negative (also referred to as a type II error), which is when a person believes “not X,” when X is true, or is cognitively unable to perceive an effect where one exists. A commonly cited example of a false-negative error is thinking an object is something other than a snake, when it is a snake. People are not prone to making this type of mistake because it would have been costly relative to the other type of mistake of thinking an object is a snake when it is not. This latter error, referred to as a false positive or a type I error, is not as costly, and so according to error management theory, we have evolved a tendency to make this error.

False negatives are not always more costly than false positives. For example, in ancestral environments, abandonment from an intimate partner may impose costs toward their offspring, due to lack of resources and protection, and so women's careful attention to selecting a mate who is committed and resourceful is important. It would therefore be adaptive for women to under-perceive a prospective mate's potential commitment (type II error or false negative – believe a person is not committed when they are), since this error would have been less costly than believing the person will be a committed partner when he is not (type I error or false positive). Erring toward false negatives would allow women to be more judicious in choosing a mate by selecting a mate with the strongest potential for long-term commitment. There is still a cost to such decisions, which is ruling out potential mates who were genuinely interested in commitment. Still, for women, erring on caution is theoretically less costly than under-inferring commitment interest. Empirical evidence supports the hypothesis that women are more prone to showing false negatives when

predicting partner commitment (Haselton and Buss 2000; Henningsen and Henningsen 2010).

Generally, according to error management theory, people may have evolved a proneness to making false negatives if making such an error minimized costs and maximized benefits relative to false positives (Johnson et al. 2013).

False Perceptions

- [False Beliefs](#)

False Positives

Victoria DeCosmo and Joseph A. Camilleri
Westfield State University, Westfield, MA, USA

Error management theory is a middle-level evolutionary theory that was proposed to explain cognitive biases, particularly systematic errors

in judgment (see Haselton and Buss 2000; ► [“Error Management Theory”](#) entry). One type of error people can make when the outcome is uncertain is a false positive (or type I error), which is when there is a belief in X when X is not true. People may be biased toward making this type of error if it is not as costly as the alternative error, known as a false negative (or type II error), which is when there is a belief in “not X” when X is true (Haselton and Nettle 2006).

A commonly cited example of a false positive is the male sexual overperception bias (see [“Male Sexual Overperception Bias”](#) entry). When determining a possible mate’s sexual interest, a false-positive error would be made if one were to perceive a potential partner as sexually interested when they are not sexually interested. Alternatively, a false negative would be perceiving a potential partner as not sexually interested when they are (Haselton and Buss 2000). Among men, due to having lower minimal obligatory parental investment, there is a greater cost to making a false negative (thinking there is sexual disinterest when there is), so Haselton and Buss hypothesized that men’s proneness to assume sexual interest, even if it leads to more false positives, is adaptive. That is, it would be more beneficial for a male to make the false-positive error than it would for him to make the false-negative error since the costs of losing face or being rejected are lower than the costs of losing the potential mate. Empirically, data support the notion that men are more prone to making this type of false positive (Haselton and Buss 2000), and researchers are now studying factors that may moderate these effects (Perilloux et al. 2012).

The logic from error management theory applies to how we engineer some products. For example, fire alarms are designed to be more prone to making false alarms (detecting a fire when there is no fire), because it would be very costly to make the other type of error (not detecting a fire when there is one). Even though there may be some costs to making a false-positive error, such as inconvenience or lost time, this cost is minimal compared to the costs of a false negative, which includes injury or even death.

Generally, according to error management theory, people may have evolved a proneness to making false positives if making such an error minimized costs and maximized benefits relative to false negatives (Johnson et al. 2013).

False-Belief Test, The

Adam See
CUNY Graduate Center, New York, NY, USA

Synonyms

[The Sally-Anne test](#)

Definition

An influential experimental paradigm designed to assess whether an individual possesses a theory of mind, based on his or her ability (or lack thereof) to attribute false beliefs to others.

Introduction

Since the late 1970s and early 1980s, the false-belief test has played pivotal roles in both developmental psychology and comparative psychology. In both fields, it has long functioned as a litmus test for assessing the presence and development of a theory of mind in human infants and great apes.

In developmental psychology, the standard method for conducting this test is widely referred to as the Sally-Anne test. Experimental data has been largely consistent insofar as the majority of children under the age of four – along with most autistic children (Baron-Cohen et al. 1985) – fail this test, while children between the ages of four and five reliably pass it (Gopnik and Astington 1988). As a result, it has long been the opinion of psychologists that normally developing children undergo a fundamental change in their cognitive abilities between the ages of four and five (Baillargeon et al. 2010). This shift is widely attributed to the emergence of a *theory of mind*, namely, the ability to attribute mental states such as beliefs, knowledge, and intentions to oneself and to others. In the twenty-first century, the value of the false-belief test to assess mind reading abilities has been widely challenged.

In comparative psychology, variations on the false-belief test have been conducted on great apes (see Krachun et al. (2010) for a review). Despite a wealth of evidence from other experimental paradigms suggesting that chimpanzees possess a theory of mind (see Call and Tomasello (2008) for a review), chimpanzees consistently fail false-belief tests. As in developmental psychology, many twenty-first-century scholars of animal cognition have questioned the value of these findings (e.g., Andrews 2015).

The Sally-Anne Test

In the standard Sally-Anne test, children are first introduced to two dolls named Sally and Anne. They are then told a simple story involving these

characters as it is simultaneously being acted out with the puppets. In this story, Sally hides a toy or treat in a box while both dolls are present and then leaves the stage. When Sally is gone, Anne then moves the desirable object from its original location to another box. Sally then returns to the scene and the infant test subject is asked, “Where will Sally look for the treat?” When the children being tested are 4–5 years old, they answer the question correctly: Sally will look in the original box. These children will also provide explanations for why Sally will *not* look in the box to which the treat has been moved. However, when children under the age of four – as well as autistic children more generally – are asked the same question, they nearly always answer incorrectly: they say that Sally will look in the new location where the treat actually is.

The common explanation for these findings is that sometime around the age of four, normally developing children begin to demonstrate an understanding of the concept of *belief* as well as the ability to apply this concept to the minds of others in order to predict their behavior. In other words, by demonstrating the ability to attribute mental states to others, children around this age are thought to have developed a theory of mind that is lacking in younger children.

The False-Belief Test in Comparative Psychology

Since the publication of Premack and Woodruff’s (1978) seminal paper, “Does the Chimpanzee Have a Theory of Mind?” the false-belief test has played an important role in the philosophy and science of animal cognition. Through a series of ingenious experiments, Premack and Woodruff concluded that an adult chimpanzee did, in fact, possess the ability to attribute mental states to others. The critical commentary for this paper proved to be extensive and highly productive for the future of work in comparative psychology. Among the most influential responses suggested that since complementary non-mind reading explanations

were possible to explain the chimpanzee’s behavior, an alternative false-belief experiment would be a far more convincing indication of theory of mind in a nonhuman species (e.g., Harman 1978).

Over the past several decades, there have been various attempts to modify the Sally-Anne test to accommodate the ecological differences between humans and chimpanzees; chimpanzees have repeated failed competitive and cooperative variations on this test (see Krachun et al. (2010) for a review). Some have taken these findings as evidence that while chimpanzees may possess a “minimal theory of mind” in the sense of attributing goals and intentions to others, humans alone possess the ability to attribute mental states such as beliefs and knowledge (Call and Tomasello 2008).

Contemporary Resistance to the False-Belief Test

In the twenty-first century, various criticisms of the false-belief test emerged that have challenged its capacity – particularly in its standard “Sally-Anne” form – to effectively test for theory of mind abilities. In an influential paper, Paul Bloom and Tim German present two reasons for why the ability to pass a false-belief test is neither necessary nor sufficient to demonstrate the capacity to attribute mental states to others (Bloom and German 2000). First, they argue that there is no reason for why one cannot at the same time possess a theory of mind in the sense of attributing beliefs to others, while likewise failing to explicitly reason about *false* beliefs. It may well be the case, they claimed, that children are attuned to the mental states of others well before being able to pass a Sally-Anne test. On this view, false-belief tests merely demonstrate that children ages four and above are able to express *in language* that which they understand much earlier in their socio-cognitive development.

This conjecture leads to the second of Bloom and German’s criticisms: that the standard Sally-Anne test actually evaluates the presence of various *non-mind* reading capacities, such as

linguistic proficiency, response inhibition, and improved memory for understanding narratives, rather than those necessarily tied to theory of mind. To this point, Kristine Onishi and Renée Baillargeon (2005) published a powerful argument suggesting that the false-belief tests place unfair cognitive demands on infants younger than 4 years old. In their *nonlinguistic* variation on the test, which relied on anticipatory looking and violation-of-expectation paradigms, Onishi and Baillargeon produced results suggesting an intuitive understanding of false beliefs in children as young as 15 months old.

With respect to the value of the false-belief test in contemporary autism research, a growing number of psychologists have likewise become skeptical of the extent of its importance (e.g., Tager-Flusberg 2007). One reason for this is that in most false-belief tests conducted on autistic children, several of these individuals *do* pass the test. One potential reason for this disparity could be, as noted above, that issues related to language development may function as confounding variables when conducting Sally-Anne-style tests on autistic children.

In terms of animal cognition research, Kristin Andrews (2015: 144) has likewise argued that since “there are possible non-mentalistic heuristics that could be applied in order to pass the test,” contemporary primatologists and philosophers should not place so much emphasis on the value of false-belief tests in comparing the cognitive abilities of apes and human infants.

Conclusion

The false-belief test has played a pivotal role in theory of mind research in both developmental and comparative psychology over the past 30 years. Although the standard false-belief test has been challenged from various angles in both fields, and while nonlinguistic false-belief tests have become increasingly popular, debates continue with respect to the most scientifically responsible interpretations of their results.

Falsifiability

Danielle Truxaw and Max M. Krasnow
Harvard University, Cambridge, MA, USA

Synonyms

[Empirical](#); [Scientific](#); [Testable](#)

Definition

Definition of falsifiable: a property of a theory such that one can conduct an empirical study that will show the theory is false if it is actually false.

Scientific theories are models for making predictions about the world. These models can be evaluated based on how accurately they predict the aspects of the world they model: models that make accurate predictions gain credibility and models that make inaccurate predictions are discredited (or “falsified”). A theory is *falsifiable* if it is possible to specify the particular conditions under which that theory would be shown to be false. If an idea is *unfalsifiable*, it makes no specific predictions, and it is impossible to test such an idea. Falsifiability is, therefore, a necessary feature of scientific theories.

Evolutionary theories are sometimes accused of being unfalsifiable and, therefore, unscientific. Often, this concern is rooted in the assumption that evolutionary theories are proposals about historical events (i.e., whether something in the past happened or not), a proposal which makes no predictions that can be tested in the here and now. However, this is a misunderstanding of the nature of evolutionary theories and the ways they can be tested. Using the adaptationist program (see listing in this volume), theories generally propose that a feature of human nature is an adaptation to solve a particular adaptive problem or a by-product of an adaptation. Each of these alternatives makes direct predictions about characteristics the feature should have – either design features to solve the adaptive problem if it is an adaption or a lack of design features to solve the by-product function and better fit to the alternative adaptation if it is a by-product.

Consider, for example, the studies showing that people automatically encode the racial identity of others (e.g., Hewstone et al. 1991). Kurzban et al. (2001) note that the ability to travel long distances is evolutionarily recent, and so our hominid ancestors were exceedingly unlikely to ever encounter someone from a different race. Thus, there should be no expectation of cognitive machinery specially designed to encode race.

Keeping track of group membership, however, would have been very informative for predicting behavior and, therefore, highly fitness relevant for our hominid ancestors. Kurzban et al. proposed that encoding race is actually a by-product of adaptations for diagnosing and tracking coalition membership in a world where patterns of cooperation and competition frequently segregate along racial lines. This theory predicts that racial encoding should decrease or disappear when race is shown to be unrelated to patterns of cooperation and competition, and this was what these authors found. So, while this theory is premised on a pattern of natural selection that happened in the ancestral past, it is directly testable by investigating the design of human psychology in the here and now and is therefore a *falsifiable* scientific theory.

Conclusion

Like all scientific theories, evolutionary theories are generative of predictions that can be falsified (in principle) by empirical data. If a theory is not falsifiable, it is not a scientific theory.

Familial Disease

► Genetic Abnormalities

Familial Violence

Janicka T. Burgess and Chloe Jex
Kansas State University, Manhattan, KS, USA

Synonyms

Child abuse; Domestic violence; Sibling violence

Definition

Physical, psychological, or sexual violence between parents, offspring, siblings, and partners within a kinship structure.

Introduction

Just as *Hamilton's rule* can be used to describe the weighing of evolutionary costs and benefits as applied to determining the likelihood of altruistic behavior among kin, it can similarly predict the likelihood of aggression between close relatives (Buss 1999). This violence is predicted through the variables of degrees of shared kinship and reproductive value (RV). These, in addition to the availability of resources necessary to survival, explain many present patterns of within-kin relationships.

Parent-Offspring Violence

Step-Parents

Research has supported the hypothesis that stepchildren are at a higher risk of abuse and homicide, a phenomenon coined the “Cinderella effect” (Daly and Wilson 1985). Further illustrating this pattern, among parents who have both

biologically related and unrelated children, stepchildren were significantly more likely to be victims of violence (Lightcap et al. 1982). For instance, Daly and Wilson (1985) compared 841 households with children ranging from 17 or younger and 99 abused children from a children's aid society in Hamilton, Ontario, Canada. Children living with just one biological or natural parent were approximately 40 times more likely to be physically abused, as compared to children living with both of their biological parents.

Biologically Related Parents

The parent-offspring conflict model (Trivers 1974) suggests that some conflicts between parents and their genetic offspring are a result of the child seeking more resources than the parent is willing or able to offer. The reproductive value of both the child and the parent are proposed as indicators of when this conflict may result in violence. The RV of a child is lowest in early life and increases with maturity. Other variables of a child's RV include quality of offspring and the resources held by parent, where a lack of either results in a lower overall value. For example, children are at a higher risk of abuse by parent when they exhibit illness or handicap in infancy and in the presence of a single parent with access to fewer resources (Lightcap et al. 1982; Daly and Wilson 1988). The decrease of parental RV with age suggests that a child would become more valuable to them as the parent becomes older, and this is reflective in the decrease of child abuse as the mother's age at childbirth increases (Daly and Wilson 1988).

Sibling Violence

Violence between stepsiblings, who share less genetic relatedness, occurs at rates significantly higher than between full siblings (Daly and Wilson 2000). When violence between siblings does occur, it can often be explained in terms of resource conflict, with potential benefits outweighing the cost of kin violence. This has been supported with, for instance, analyses of sibling conflicts over inheritance, money, and

land; the most often cited cause of serious sibling conflict (Daly and Wilson 1988).

Families facing economic challenges are also more likely to have higher rates of sibling violence. This goes back to the idea of resource conflict mentioned above (Daly and Wilson 1988). For example, Hardy (2001) found that “financial and business stresses, and any work transitions in the family, increase the likelihood of sibling violence” (p. 499). These stressors can increase the social isolation of the family, which fosters an environment where sibling violence is more likely to occur. Having boundaries between the family and outsiders (i.e., religious affiliations, etc.) is also responsible for contributing to higher rates of sibling violence.

Partner Violence

Much of violence against a partner can be explained by noting implications from the principal of male paternal uncertainty. Paternity uncertainty is the possibility that a putative father is not actually the biological father of a child. Through acts of mate guarding, the fertilization by a particular male can be better protected, a countermeasure against the risk of providing parental investment to a child fathered by a different individual (Wilson and Daly 1993). These tactics to limit partner autonomy and secure paternity have been associated with men’s violence against romantic partners. (Buss et al. 2008). Consistent with this pattern, women of reproductive age are much more likely than older women to be victims of domestic abuse (Peters et al. 2002). These findings support an interpretation that sexual jealousy-fueled violence is not itself an adaption but instead is often the byproduct of mating strategies.

Conclusion

Instances of violence can occur between individuals that are genetically related, non-genetically related and involved in domestic relationships. These types of violence incidents are usually the result of many different aspects influencing

whether individuals are more likely to be altruistic or aggressive toward one another. For example, individuals that are genetically related are more likely to be altruistic to one another, while non-genetically related individuals are more likely to experience higher rates of abuse. Another important factor is the availability of resources and how that influences the pattern within the different types of relationships. In conclusion, there are many different factors that influence the nature of relationships and potential acts of violence within them.

Definition

People who are related by descent (including adoption) and marriage.

Introduction

In every human society, people identify certain others as family. These social relationships are an important part of people's lives, with family (or descent) groups being the main unit of social organization in many societies. While kinship is a human universal, norms about who is

considered family, and the expectations and obligations of family members vary cross-culturally. Family tends to include those related by descent and marriage. Kin are typically categorized as *consanguineal*, meaning related by descent, or *affinal*, meaning related by marriage. Given that humans are a social species, family relationships influence many aspects of people's lives.

Evolutionary Perspectives

When examining family from an evolutionary perspective, researchers tend to focus on those individuals who are biologically related. This is because help to kin, and its amount, can be predicted from the inclusive fitness benefits of helping behavior. In other words, an individual can propagate one's genes not solely through direct reproduction but through helping individuals who share the same genes. Hamilton's rule states mathematically when we expect biological kin to help. It specifies that kin should help one another when the benefit to the recipient (B), devalued by the probability that the individuals share a gene by common descent (r) is greater than the cost (C) to the individual providing the benefit ($B \cdot r > C$) (Hamilton 1964). Costs and benefits should be conceptualized as reproductive success gained or lost, but such measures are nearly impossible to calculate in humans. There is substantial evidence showing that kin provide help to one another and that individuals are more likely to help closely related kin than distantly related kin, both in humans and in other species.

Evolutionary theory has a harder time explaining help among family members that are not biologically related, although this helping behavior clearly occurs. One of the main avenues for creating such kin ties among unrelated individuals in humans is marriage. There is some evidence that people's helping behavior towards affines follows similar patterns as those for genetically related individuals (Burton-Chellaw and Dunbar 2011), even though other mechanisms must be at work. Helping which cannot produce inclusive fitness benefits has been explained via other mechanisms such as reciprocal altruism,

indirect reciprocity, norm enforcement, or increased reputation through “showing off.” One of the most impressive forms of nonbiological kin helping is that of adoption, where individuals provide extensive parental investment to unrelated offspring (and offspring are unlikely to ever “repay” their adoptive parents). This type of behavior cannot be explained via reciprocal altruism or other mechanisms and may be purely altruistic. Evolutionary explanations for adoption include reducing social stigma associated with not reproducing (where, in some societies, social status is mainly achieved through one’s reproduction) or the adaptive desire to parent being co-opted for care of nonbiologically related individuals. Empirical studies have compared parental investment of adopted versus biological children and found mixed results. Evidence from an American sample showed adopted children receive *more* investment than biological children counter to predictions by kin selection theory (Gibson 2009). This may be partially explained by the more negative outcomes experienced by adopted children and suggests a greater need for investment by adopted children than biological ones. In contrast, data from Oceania suggests that adopted children (who tend to be related but less so than offspring) tend to receive less land inheritance than biological offspring (Silk 1980). There may be inherent differences between investment patterns of parents who seek out and invest significant time and money to adopt versus those who do not.

Humans as Cooperative Breeders

Given that human females *need* help from others to raise multiple dependent offspring, Hrdy has proposed that humans are cooperative breeders (2005). In most nonhuman ape species, females raise offspring without help from others and those offspring are independent food producers once they are weaned. This is in a sharp contrast to human children, who at the age of weaning still have many years of food dependence. Estimates suggest that children may not produce as much food as they consume until

15–20 years of age (Kaplan 1994; Lee and Kramer 2002). Given the unique human life history of short birth intervals and a long period of dependence, individuals other than the mother, including fathers, grandparents, older siblings, other kin, and even unrelated individuals help to raise children. While the help received allows women to have faster reproductive rates, it is necessarily balanced by more time in non-reproductive stages allowing both juveniles and post-reproductive women to help raise reproductive-aged women’s offspring.

Kin Conflict

While there is a wealth of evidence documenting the cooperation that exists between kin, there is also significant conflict. We expect conflict to occur since individuals (other than identical twins) are more related to themselves than to their kin. This can result in conflicts between mothers and offspring, siblings, pair-bonded parents (who may not be related at all, but have a common interest in their joint offspring), among others. Intergenerational conflict models have also been developed to potentially explain human life history characteristics like menopause and age at first birth. These models assume reproductive conflict – where limited resources result in competition among kin to reproduce. By examining how much each individual has to lose (genetically) by not reproducing, these models argue that the individual with *more to lose* reproductively will be likely to win these conflicts. For example, Cant and Johnstone (2008) show that under conditions of reproductive conflict and patrilocal post-marital residence, models predict that daughters-in-law have “more to lose” genetically and will therefore reproduce, while their mothers-in-law will opt to stop reproducing, possibly leading to menopause. There may also be kin conflict that occurs at the community level, where individuals who do not migrate (given sex-biased dispersal patterns) are less likely to compete since their local competitors will be kin. These models have been developed to explain behavior in both human and nonhuman species.

Role of Family Structure on Pubertal Timing

Extensive research has examined how early life events and family structure may influence a person's transition to adulthood (indicated by age at puberty), reproductive timing, and reproductive rate. These studies conceptualize reproductive outcomes as markers of an individual's reproductive strategy. Empirical results show (particularly in high-income societies) that girls who grow up without their biological father in the household (typically the result of parental divorce) tend to have earlier age at menarche (Webster et al. 2014). These empirical findings may be the result of individuals using cues of their environmental harshness and uncertainty to accelerate their reproductive careers to maximize reproductive success, given a high-risk environment (Ellis et al. 2009), focusing their reproductive careers to a time when they can expect to have the most help from their main alloparent – their mothers (Geronimus 2003), or an outcome of intergenerational kin conflict. Under conditions of reproductive conflict between mothers and daughters, if daughters expect their mothers to produce full-siblings (because their biological parents remain pairbonded), daughters may opt to delay reproduction and instead act as an alloparent to a full-sibling (since an individual is equally related to an offspring as a full-sibling). Based on the model, daughters should be less willing to delay reproduction if their mothers will produce half-siblings, since these siblings will be related by only half as much (Moya and Sear 2014). Future research should attempt to test these different theoretical underpinnings of the empirical finding that family structure in high-wealth countries influences menarcheal timing.

Conclusion

Family is considered important in all human societies. While evolutionary researchers tend to focus on biological relatedness, human kinship also includes individuals who are not biologically

related. Empirical research has demonstrated the role of biological relatedness in predicting helping behavior, but less is known about patterns of help among nonbiological family members. Some research has examined differences in investment among biological and nonbiological offspring, showing that in some contexts, nonbiological offspring receive at least as much (or more) investment than biological offspring, counter to evolutionary predictions. While kin cooperation is evident, it is also important to recognize and understand kin conflict that can occur at dyadic, family, and community-levels. Finally, understanding the different theoretical frameworks by which kinship influences human behavior and life history allows for different predictions to explain similar empirical phenomenon.

Fast Versus Slow Strategies

Marjorie L. Prokosch and Emily Corrigan
Department of Psychology, Texas Christian
University, Fort Worth, TX, USA

Synonyms

[Life history strategies](#); [r/K-selection strategies](#)

Definition

Fast and slow life history strategies are predictable patterns in energy allocation that fall on a life history “continuum” of how organisms allocate their limited energetic resources between the competing demands of somatic development and reproduction so as to maximize fitness in their local ecology. Strategies with a bias in effort made towards somatic development are called *slow* life history strategies, while strategies with a bias in effort made towards reproduction are called *fast* life history strategies.

Introduction

Life history theory states that energy is inherently limited and that tradeoffs must be made in how energy is spent because organisms cannot simultaneously invest energy into multiple competing needs. Thus, organisms should make tradeoffs in allocations that best help to enhance fitness in their local ecology (Roff 1992). The predictable patterns of tradeoffs made across organisms’ lifespans can be thought of as falling on a spectrum, ranging from “fast” to “slow.” Strategies towards the fast end of the spectrum favor *quantity* of reproductive opportunities over quality, whereas slower strategies favor reproductive *quality* at the cost of quantity. There is variation in the type of life history strategy adopted (faster or slower), both between species but also within species. For example, while humans as a species err on the slower side of the life history strategy

Fast Versus Slow Strategies, Table 1 Contrasts between fast and slow life history strategies in humans

	<i>Fast strategy</i>	<i>Slow strategy</i>
Development and decision-making		
<i>Juvenile period</i>	Shorter	Prolonged
<i>Pubertal timing</i>	Earlier	Later
<i>Physiological aging</i>	Faster	Slower
<i>Reward orientation</i>	Riskier, more immediate rewards	Risk averse, delayed rewards
<i>Cooperation</i>	Low trust, low investment	High trust, high investment
Mating and parenting		
<i>Sexual debut</i>	Earlier	Later
<i>Age of first reproduction</i>	Earlier	Later
<i>Partner number</i>	Greater	Later
<i>Offspring number</i>	Greater	Fewer
<i>Romantic relationships</i>	Short-term orientation	Long-term orientation
<i>Offspring investment</i>	Lower	Higher

spectrum (e.g., a bias towards somatic effort), there is considerable variation within humans in life history strategy.

Two factors in the local ecology that calibrate organisms’ life history strategies are *harshness* and unpredictability. Environments that are harsh and unpredictable in nature tend to promote the adoption of faster life history strategies, where effort is made towards reproducing before succumbing to morbidity or mortality. Environments that are benign and predictable tend to favor the development of slower life history strategies, where effort is allocated towards growth and maintenance so as to maximize resource acquisition and offspring competitiveness (Ellis et al. 2009). Below, this article will summarize some of the empirically supported differences in fast versus slow strategists’ physiology and psychology (see Table 1 for a summary).

Development

Because organisms falling on the “faster” end of the life history continuum invest a great deal of effort in mating, they tend to experience shorter juvenile periods and earlier puberty than those pursuing a slower life history strategy. Faster life history strategies tend to favor investing less time in a juvenile period (e.g., childhood) by speeding up development to reach sexual maturity sooner because earlier

maturity enables organisms to begin reproducing earlier and more often than organisms that do not mature as quickly (Ellis 2004). Such shifts in development increase the chance that one will be able to successfully reproduce (and do so often enough to produce surviving offspring) before succumbing to morbidity or death in harsher environments (Roff 1992).

Mating

In addition to earlier pubertal timing, people (and organisms) that pursue a faster life history strategy tend to sexually debut earlier than individuals following slower life history strategies (Belsky et al. 1991). Further, faster strategists tend to have an earlier age of first reproduction and a greater number of lifetime sexual partners than slower strategists (Wilson and Daly 1997). Relatedly, research has found that slower strategists, who form longer-term pair bonds with fewer partners, are more selective when choosing prospective mates, with slower strategists (a) being more likely to engage in positive assortative mating and (b) being choosier about mating opportunities than faster strategists. Some research indicates that these looser pair bonds may be related to differences in attachment styles, with insecure attachment styles being represented at higher rates among people from harsh and unpredictable environments (Chisholm et al. 2005). It is

hypothesized that for faster strategists adopting such mating choices (e.g., looser pair bonds, less selectivity in mate choice, greater desire for variety) would favor having greater numbers of children with genetically diverse partners – an adaptation that would help to ensure some offspring will survive to reproductive age in a harsh and unpredictable environment (Ellis et al. 2009; Roff 1992).

Parenting

Life history theory predicts that individuals in harsh and unpredictable environments will favor having more offspring sooner because such *fast* strategies would favor the chance that (a) one will reproduce successfully before dying and (b) at least some of one's offspring will possess the genotypic or phenotypic qualities needed to survive in an uncertain future (Chisholm et al. 2005; Ellis et al. 2009). Having more offspring at an earlier age comes at the cost of being able to invest less in each individual offspring. However, in environments where future survival is more certain, it is more beneficial to reproduce later and in fewer numbers while investing more in the upbringing of each individual offspring (Roff 1992). People following faster life history strategies (e.g., those reared in more impoverished, dangerous regions) tend to have more children at an earlier age and have looser attachments to these children than people who have adapted slower strategies (Belsky et al. 1991; Wilson and Daly 1997). Faster strategists may be more prone to engaging in harsher (e.g., authoritarian), less consistent and sometimes “dysfunctional” child-rearing behaviors, which increase the chances that their children will also develop faster life history strategies (Belsky et al. 1991). Conversely, slower strategies are more likely to demonstrate affection for offspring, encourage achievement, and invest resources more heavily in their children. Finally, faster strategists may be more vulnerable to environmental stressors in adulthood, and thus are more likely to shift resources towards hastening reproduction in response to cues of harshness and uncertainty in adulthood than are

individuals from more benign environments (Griskevicius et al. 2011a).

Psychological Differences

Another way that differences between fast versus slow life history strategies may be conceptualized is by envisioning strategies as investments in present versus future mating effort. Faster strategists are more likely to adapt psychology and behaviors that favor more immediate reproduction, while slower strategists adapt those that favor later reproduction (Ellis et al. 2009). Future survival and reproduction are often uncertain for those pursuing faster strategies; thus, fast strategists tend to place a greater emphasis on the present, preferring more immediate rewards to holding out for rewards they might not live to reap. Research consistent with this hypothesis reveals that faster strategists tend to engage in more risky, gain-seeking behaviors, exhibit greater impulsivity, and are more likely to discount the future when evaluating rewards (Griskevicius et al. 2011b). Slower strategists, who hail from more certain environments, tend to be more risk averse and more forward thinking when evaluating both time horizon and reward options, which manifests in lowered risk taking and heightened ability to delay gratification. Such divergences are most pronounced in response to cues of harshness and uncertainty in adulthood and may be mediated by differences in perceived control.

In a related vein, the investment in immediate versus delayed reproduction may also manifest in the cooperative strategies that people pursue. For example, people pursuing faster life history strategies are more likely to engage in behaviors that are impulsive, rebellious, or deceitful in nature than slower strategists – behaviors that would favor immediate gains in resources for oneself but not the long-term preservation of coalitions with other people. On the other hand, slower strategists tended to place higher investment in close relationships, trusting individuals more and forgiving transgressions more often than those pursuing a faster strategy.

Health

Although earlier puberty offers an earlier chance for reproduction, research indicates that the shortened developmental period associated with faster life history strategies comes at the cost of building a more robust body for adulthood (Rickard et al. 2014). For example, the experience of psychosocial and physical stressors in early childhood (e.g., lower socioeconomic status, poor nutrition, abuse) have been linked to HPA axis dysregulation, a “pro-inflammatory” phenotype, and consequently higher risk of contracting heart disease, diabetes, and certain cancers, even in those who attain improved circumstances in adulthood (Miller et al. 2011). In short, although pursuing a fast life history strategy may lead to reproductive benefits in the short term, it may also be linked to chronic diseases and inflammation later in life.

Conclusion

The type of life history strategy that an individual adopts can have profound implications for one’s physiology, psychology, and reproductive outcomes. As such, life history theory represents a powerful predictive framework that can be used to predict individual differences in a wide range of traits and behaviors. Although both fast and slow strategies can both lead to long-term reproductive success in harsher versus more benign ecologies (Roff 1992), further investigation into the trade-offs that come with the pursuit of each strategy and their longer-term consequences for health and well-being represents an important area of future research. As such, greater application of life history theory with existing research paradigms in the fields of psychology, neuroscience, and medicine are integral.

Fat

- Body Reserves and Food Storage

Fat Man, The

Giovanni Randazzo

Department of Psychology, Oakland University,
Rochester, MI, USA

Synonyms

Footbridge; Man with backpack

Definition

The fat man is a variation of a choice in the moral dilemma called, “the trolley problem” where a fat, large, or man with a backpack can be pushed or dropped onto tracks to stop a trolley.

Introduction

The trolley problem is a moral dilemma used first by philosophers starting in 1967 and then adopted by psychologists to examine moral thinking in humans (Cathcart 2013). The original problem was made by Philippa Foot in a philosophical paper about abortion. The original problem was simply many variations of a scenario where someone had to make a choice of killing one to save five, one of which was switching a tram to a different track (1967). The current fat man variation is generally stated as such:

You are standing near a trolley track, there is a trolley heading down the track toward five workers who are unaware of the trolley and whom will die if nothing is done. There is a fat man next to you, large enough to stop the trolley if pushed onto the tracks; this will kill the fat man. Do you stop the trolley by pushing the fat man onto the tracks or let the trolley hit the five workers on the track (Cathcart 2013)?

The Fat Man

This moral dilemma has many variations including the fat man being a man with a large backpack instead, the man being on a separate track that the

trolley can be turned onto, the fat man and participant being above the track on a footbridge instead of next to the track, or that the fat man can be dropped through a trap door on the footbridge onto the track by pulling a lever (Cathcart 2013; Greene 2013).

From an evolutionary perspective, the fat man variation is good for analysis of moral and spatial thinking. For instance, people will rarely choose to push the fat man onto the tracks, but more people are willing to pull a lever to open a trap door dropping the fat man, and many more are willing to switch the trolley onto a different track killing only one instead of five (although this is still only 20 % of people; Greene 2013).

Joshua Greene, April Bleske-Rechek, and Peter Singer are examples of psychologists and philosophers whom have used an evolutionary perspective in their analysis of the dilemma regarding the fat man variation.

In Joshua Greene’s *Moral Tribes* (2013), Greene takes an in-depth evolutionary approach to the trolley problem and its many variations, with a large focus on the fat man variation, or in his synonymous version of the problem, “man with backpack.” Green explains that only 20 % of people are willing to push the man onto the tracks to save the five workmen. Pushing the man with a backpack or the fat man saves the most lives, but people have a negative emotional reaction to this. This negative reaction is reduced when the man is described as being on a separate track. When given this scenario involving a second track, known as the loop variant, 53 % (Bleske-Rechek et al. 2010) to 86 % (Greene 2013) of participants sacrificed the man – single man to save the five.

Both Greene (2013) and Singer (2005) argue that the reason for the variance in negative emotional reactions sacrificed the single man to save the fat man is based on innate moral responses or empathy, which is further affected by our spatial reasoning. Pushing the man onto the track is a personally direct action, whereas pulling a lever is an indirect and distant action. This empathy response makes pushing the fat man difficult, but pulling the lever an easier choice since the five and one share distance. Greene (2013) provided

support for this hypothesis when he gave the trolley problem to psychopaths/sociopaths, finding that they nearly all answered to push the man to save the five regardless of the personal distance involved.

Conclusion

The fat man variation of the trolley problem is used to understand moral thinking in humans. The fat man variant is the general situation in the trolley problem that involves dropping or pushing a man onto the tracks to stop the trolley as opposed to redirecting the trolley. The emotional response to not push the fat man is stronger when the man is younger, more related, or a potential mate, suggesting that moral reasoning varies according to context and the traits of the potential victim (Bleske-Rechek et al. 2010).

Father Absence

Lynda Boothroyd

Department of Psychology, Durham University, Durham, UK

Definition

The term “father absence” is generally taken to indicate that an individual has spent some or all of their childhood with a nonresident biological father. While this can be due to paternal death, the majority of research concentrates on cases of non-resident fathers who are separated from (or were never pair bonded with) the individual’s mother.

Introduction

Evolutionary research into the impacts of father absence on offspring has largely fallen into two camps, which one might roughly characterize as developmental psychology versus behavioral ecologically, respectively, and investigated two sets of outcomes: offspring reproductive outcomes and offspring condition.

Reproductive Development of Offspring

A considerable body of work has amassed investigating the reproductive outcomes of children (mainly daughters) of father-absent households in the West. Although interest in the links between father absence and girls’ sexual behavior dates back to developmental psychologist Marion Hetherington’s 1970 observation that daughters of divorced, but not widowed, mothers displayed elevated sexual behavior as teenagers, the more recent contribution of evolutionary research was,

at its core, to propose that early father absence (potentially among other stressors) may accelerate pubertal development and the onset of sexual behavior in daughters as a response to environments which were unstable and/or unlikely to support viable pair-bonds (Belsky et al. 1991; Draper and Harpending 1982). As such, maximizing reproductive success might best be achieved, for girls, by starting reproduction earlier.

Studies of the association between father absence and puberty in girls typically report father-absent girls experiencing first menses around 6–12 months earlier than their father-present counterparts. Webster et al. (2014) published a meta-analysis of this literature and reported a significant mean weighted association of $r = 0.14$ between father absence and earlier menarche. This suggests that approximately 5.6 % of variance in age of menarche may be explained by the presence or absence of the biological father from the home in early childhood. Alongside earlier menarche, father absence in Western samples is also typically associated with earlier sexual activity and earlier reproduction in women (e.g., Ellis et al. 2003; Boothroyd et al. 2013). The dominant current explanation for these phenomena focuses on the influence of stress on the maturation of the endocrine system (see, e.g., Ellis 2013). It is particularly in the context of this latter potential mechanism that father absence is posited as one among many potential stressors, and adaptive hypotheses center around the fitness benefits of either successfully predicting the harshness of the environment in which reproduction will take place (standard psychosocial acceleration models) or of responding appropriately to the effects of the current environment on one's own condition (internal prediction models: Rickard et al. 2014). The key factor from either perspective is that father absence may trigger earlier menarche and earlier reproduction as a means of maximizing reproductive success when faced, in some form, with harsh environments.

There has been less attention to the sequelae of father absence in boys. Although father-absent boys are more likely to go on to be absent fathers themselves (see, e.g., Jaffee et al. 2001), and to reproduce earlier in the West, the literature regarding timing of puberty in boys is sparse and the

results decidedly mixed, with some authors even finding father absence to predict later puberty in boys (e.g., Sheppard et al. 2015). Several authors have argued that a sex difference in responses to father absence is consistent with sex differences in predictors of reproductive success, with males perhaps benefiting most from building competitive advantage rather than accelerating reproduction in harsh and/or low-paternal-investment environments (see Draper and Harpending 1982; James et al. 2012).

Behavioral Ecology Approaches to Reproductive Development in Offspring

Behavioral ecology approaches to father absence have tended to concentrate on offspring outcomes in terms of survival and fertility, often with the primary goal of understanding drivers of parenting behavior, rather than drivers of child development. The remarkable feature of this particular literature is the extent to which father absence (or presence) often makes very little difference to offspring at all. In a wide-ranging systematic review, Sear and Coall (2011) found that, while among low-fertility samples (i.e., “WEIRD,” Western, educated, industrial, rich, democratic (Henrich et al. 2010)) the presence of fathers appeared to have an inhibitory effect on fertility (indexed by less teenage pregnancy, later first birth) as discussed above, fathers in high-fertility samples had a facilitatory or no effect on offspring fertility. Where there were significant associations, present/living fathers were typically associated with earlier first birth and a greater number of children born, the former of which is directly at odds with the data from Western samples. Perhaps the most likely explanation for these results is that in small-scale and high-fertility populations, the most critical contribution of secondary caregivers (as fathers tend to be) is to supplement the child's nutritional or social status in a manner which makes a much greater contribution to maturation and/or marriageability than any variation induced by psychosocial stressors. Indeed the simple fact that girls in WEIRD samples display considerably

earlier menarche than in small-scale societies suggests that considerable nutritional constraints on menarche have been lifted in the West and, as such, raises the question of how much these WEIRD samples can tell us about ancestral selection pressures on reproductive development.

Mortality and Morbidity Outcomes in Offspring

One factor which unites both the behavioral ecology and evolutionary developmental psychology approaches to father absence is an interest in how paternal care may influence offspring viability and condition. Indeed, as discussed above, one strand of developmental interest in father absence argues that earlier menarche in father-absent daughters is an adaptive response to the effects of adversity on the well-being of offspring. There are a number of large epidemiological studies in the West which find an association between parental divorce (usually synonymous with father absence in these data) and poorer adult health, shorter adult height, and shorter life expectancy in offspring (e.g., Maier and Lachman 2000; Schwartz et al. 1995; Sheppard et al. 2015). In some samples, the associations between family structure and later offspring outcomes were mediated by stressors inherent in, or other sequelae of, the separation (e.g., Maier and Lachman 2000), which is consistent with other evidence suggesting relational stress in childhood may be associated with health outcomes in later years.

Unlike the data regarding reproductive development, these associations are not limited to WEIRD samples. For instance, Flinn and England (1997) assessed the living conditions of children and adolescents living in a village in Dominica and took regular saliva samples (several times a day for multiple days) to assess their levels of cortisol (a stress-related hormone) and monitored children's health. The population they studied was matrilocal and the parenting conditions were very varied; half of children (approx. 54 %, averaging across 4 study seasons) were living with their mother and their biological or stepfather, while a further 12 % lived alone with a single parent. The

remainder of the children lived with mother and kin, grandparents, distant kin, or nonrelatives. Flinn and England found that children living without their biological father experienced significantly more days of illness and had significantly higher cortisol levels than those living with both parents (even if their father was often absent from the home, e.g., for work or after rows). They also found a moderate positive correlation (0.35) between levels of cortisol and self-reported days of illness, again supporting the suggestion that any impacts of father absence on offspring health are mediated by stress.

The impacts of father absence on *mortality* in preindustrial populations, however, are rather more ambiguous. While there are notable examples of father absence or death of father being associated with slightly higher offspring mortality in both anthropological and historical records, Sear and Coall (2011) found that in more than half of small-scale societies for which data were published, father loss (by death or absence) had no significant link with offspring survival.

Conclusion

Overall, these data suggest that father absence may sometimes be detrimental to offspring survival (and ergo adaptive benefits of long-term pair-bonds may certainly include greater reproductive success in some ecologies), but is perhaps more likely to impact on offspring condition. This may be mediated by stress, and while in WEIRD samples, daughters may be able to offset any loss of condition via accelerated reproductive development, there is no evidence that sons or non-WEIRD daughters do the same. The primary challenge facing the literature at the current time may be to comprehensively unite these diverse results in a single explanatory framework.

Father Absence and Stress Reactivity

Randi Proffitt Leyva and Hannah Bradshaw
Texas Christian University, Fort Worth, TX, USA

Synonyms

Fatherlessness; Stress response system

Definition

The absence of a father during the formative childhood years.

The functioning of the stress response system in response to stressors.

Introduction

According to the Adaptive Calibration Model (ACM), an evolutionary theory of human development, early childhood environments shape an individual's stress responsivity in a functional manner in preparation for the anticipated social

and physical adult environment (Del Giudice et al. 2012). Although there are many factors that affect the relative stressfulness of childhood environments, one significant aspect is father absence. Unlike many mammals, humans generally engage in bi-parental rearing of children, with both the mother and father investing heavily in the development and survival of the offspring (Lovejoy 1981). Lack of paternal investment inherently engenders a stressful rearing environment marked by access to fewer resources, increased financial hardship, and less parental care for offspring. Indeed, children growing up in father absent homes are found to experience higher levels of anxiety, stress, and depression (Draper and Harpending 1982; Weinraub and Wolf 1983), as well as increased impulsivity, lower problem-solving abilities, poorer psychological adjustment, increased risks of incarceration and substance abuse, and for girls, a host of precocious sexual outcomes.

The Effect of Father Absence on the Stress Response System

The stress arising from father absence during childhood triggers calibration of the stress response system, known as the hypothalamic-pituitary-adrenal (HPA) axis. Stressful events activate the HPA axis, which leads to release of the hormone cortisol into the bloodstream. Chronic activation of the HPA axis, and hence high levels of cortisol, has a wide range of negative health effects, including downregulation of the immune system, increases in heart rate and blood pressure, reduction in metabolic processes, a reduction in growth, and a reduction in somatic resources to invest in reproduction (Segerstrom and Miller 2004). Children who grow up in father absent households or those characterized by unstable parental pair bonds exhibit highly abnormal cortisol levels, which has profound negative impacts on health (Flinn and England 1997). Although both boys and girls show increased stress reactivity in response to father absence, some research suggests that the male neuroendocrine response (compared to that of females) may be more

pronounced by paternal absence, with males exhibiting more abnormality in cortisol levels during childhood, adolescence, and continuing into adulthood (Flinn et al. 1996). While the neuroendocrine response to father absence is more marked in sons, there is much evidence indicating that father absence has a discernable impact on the life history of daughters as well.

The Effect of Father Absence on Reproductive Outcomes

According to paternal investment theory, paternal disengagement, especially in the early years of life, serves as a signal to daughters that the local mating ecology is one in which male investment is unreliable and unnecessary. For daughters of absent fathers, a robust body of evidence finds that father absence predicts earlier pubertal timing, earlier sexual debut, and earlier age at first reproduction (Ellis 2004; James et al. 2012). Consequently they also tend to have a higher number of sexual partners and lower expectations of investment in offspring by mates (Draper and Harpending 1982). Research indicates that father absence in females increases subsequent sexual risk taking, leading to risky promiscuous mating behavior, and also negatively influences the later family environment in which their offspring are reared (Quinlan and Flinn 2003). This mating behavior contributes to an intergenerational cycle of early calibration of father-absence-related stress reactivity and fast sexual strategies in single-mothers and their children.

Conclusion

In sum, father absence causes increased stress experienced during childhood, leading to heightened stress reactivity and precocious sexual behavior amongst daughters. It is important to note that calibration of the stress response system is adaptive for preparing the child for the ostensibly stressful adult environments to come. Because paternal presence and investment is vitally important during development, father absence during

childhood provides a cue that the environment is harsh and unstable. Therefore, it may be adaptive for individuals that experience father absence to develop a stress response system that would promote survival in such an environment and for women, encourage early reproduction of offspring.

Definition

Although all grandparents share an average of 25% of their genes with their grandchildren, they are not in an equal position relative to their

grandchildren. Due to paternity uncertainty, sex-specific reproductive strategies, and age, the unequal positions of the grandparents are most evident between a father's father and a mother's mother. A mother's mother is typically the most involved with her grandchild's life and a father's father is the least involved.

Introduction

Hamilton's rule predicts that individuals invest more in their close kin than in distant kin or nonkin when all else is equal (Hamilton 1964). Grandparents share approximately 25% of their genes with their grandchildren. Therefore, one may assume that different grandparent types (i.e., mother's mother, mother's father, father's mother, and father's father) invest nearly equally in their grandchildren. However, due to paternity uncertainty (or relationship certainty), all grandparents are not in an equal position relative to their grandchildren. In the case of grandparents, paternity uncertainty means that no uncertain links exist between a grandchild and the mother's mother. A mother's father and a father's mother have one kinship link with paternity uncertainty and a father's father is in the most uncertain position because he cannot be totally sure that he is related to his son and his son cannot be sure that he is related to his child. Therefore, fathers' fathers have two uncertain links of paternity and paternity uncertainty creates the most bias between a mother's mother and a father's father. Evolutionary theory predicts that because of paternity uncertainty, a mother's mother should invest the most in grandchildren and a father's father should invest the least.

Paternity uncertainty is closely related to sex-specific reproductive strategies. Sex-specific reproductive strategies derive from the fact that due to pregnancy and lactation, for example, a single offspring is more costly for women than for men, meaning that maternal investment is more obligatory than paternal investment, which can be facultative (Trivers 1972). Similarly, with paternity uncertainty, sex-specific reproductive strategies predict biases in grandparental

investment between grandmothers and grandfathers and between maternal lineage and paternal lineage.

Due to differences between men and women in the mean age at marriage and the mean age at first birth, maternal grandparents are usually younger than paternal grandparents and the age difference is the greatest between the mother's mother, who is likely to be the youngest of the grandparents, and the father's father who is likely to be the oldest (Strassmann and Garrard 2011). Therefore, in addition to paternity uncertainty and sex-specific reproductive strategies, grandparental age may also create biases between a mother's mother and a father's father. Grandchildren typically have the most shared years of life with their mother's mother and the least, if any, with their father's father.

Empirical Evidence

One of the most common findings in grandparent studies is that the mother's mother typically invests the most, followed by the mother's father and the father's mother, but the father's father usually invests the least (see Coall and Hertwig 2010 for review). This is consistent with the assumption predicted by paternity uncertainty. The pattern of biased grandparental investment tends to hold even in countries with no explicit preference for matri- or patrilineal family relations and when several potentially confounding variables are controlled for (Danielsbacka et al. 2011). Although age differences are evident between grandparents, especially between a mother's mother and a father's father, prior studies have shown that mothers' mothers invest the most in their grandchildren and fathers' father invest the least, even after the grandparental age is controlled for (Euler 2011). In addition, the pattern of biased grandparental investment is not limited only on grandparents' reports. Grandchildren and parents (i.e., the middle generation) typically assess the investment from the maternal grandmother to be the largest and from the paternal grandfather the smallest (Danielsbacka and Tanskanen 2012; Danielsbacka et al. 2015).

In addition, divorce and re-marriage in parental and in grandparental generations may further increase the bias between a mother's mother and a father's father because the negative effect of divorce on family relationships is usually stronger on fathers than on mothers (Euler 2011). Divorce can also occur in the grandparental generation and divorced grandfathers tend to have less contact with their grandchildren than married grandfathers, but divorce did not matter in grandmothers regarding their contact with their grandchildren (Danielsbacka and Tanskanen 2016).

Conclusion

The pattern of biased grandparental investment is widely studied in contemporary western societies. The most evident finding is the bias between a father's father and a mother's mother, which is realized in grandparental investment; a mother's mother typically invests the most and a father's father the least. In evolutionary psychology, the pattern and especially the difference between a mother's mother and a father's father is usually explained by paternity uncertainty and sex-specific reproductive strategies. In addition to the sex, lineage, and the degree of relationship certainty, the age difference between a mother's mother and a father's father typically favors the mother's mother, who is usually the youngest grandparent while the father's father is the oldest.

[Boar effect](#); [Novel male effect](#); [Socioendocrinology](#)

Definition

The term “Father-Absence and Stepfather Presence” refers to a familial situation in which an individual is reared in a household before puberty without the biological father present and with the presence of a genetically unrelated male adult.

Introduction

Life history theory suggests that organisms possess phenotypic plasticity for various life history traits as a function of ecological conditions. To enhance fitness, “decisions” must be made concerning the trade-off between present and future reproduction, between quantity and quality of offspring, and between mating and parenting effort (Kaplan and Gangestad 2005). Subsumed within life history theory are theories that posit that familial relations and parental investment (e.g., Draper and Harpending 1982) or a broader range of familial stressors including family composition (e.g., Belsky et al. 1991) prime certain female reproductive strategies such as the timing of puberty or menarche. More specifically, it has been proposed that early psychosocial stressors in the family environment characterized by conflict, divorce, insecure attachments, lack of supportive and positive relationships, and unpredictable resources lead to an accelerated developmental trajectory that results in an earlier pubertal maturation and initiation of sexual behavior. More stable and supportive family environments code for later puberty and sexual behavior (Belsky et al. 1991).

Father Absence

The most consistent socioendocrinological finding in the literature is the correlation between biological father absent (FA) and early menarche in girls (Ellis 2004; Moffitt et al. 1992; Romans et al. 2003; Surbey 1990), also verified in a recent meta-analysis (Webster et al. 2014). This effect has been found in both prospective longitudinal studies (Campbell and Udry 1995; Ellis and Garber 2000) and in large sample retrospective studies (Matchock and Susman 2006; Quinlan 2003; Surbey 1990), although a few studies have found no effect for father absence on age of menarche (Anderson 2015). Moreover, some studies have found that the longer the father has been absent from the home, the earlier the menarche (Moffitt et al. 1992; Surbey 1990).

Etiological explanations to explain the link between father absence and age of menarche include the psychosocial acceleration theory of Belsky et al. (1991), girls learn that the family environment is unstable and untrustworthy and accelerate puberty; parental investment theory, father investment is reduced in FA families, so girls mature early (Ellis 2004); genetic explanations, early maturing mothers possess genes that contribute to both early menarche and an earlier more unrestricted sociosexuality (or an X-linked androgen receptor gene in the father; see Comings et al. 2002); pheromonal explanations, Matchock and Susman (2006) and Ellis (2004) proposed that delaying menarche when reared next to biological fathers may be an anti-inbreeding strategy, perhaps mediated by inhibitory olfactory cues from the father.

Father Absence and Stepfather Presence

The effect of both FA and stepfather presence (SFP) on menarcheal age has not systematically examined in enough detail to provide a clear picture of this relationship. Many studies do not differentiate between FA and FA-SFP families, and sample sizes tend to be prohibitively small when FA girls are divided into FA and FA-SFP groups. There is also not a consensus on the evolutionary underpinnings for an effect of SFP on menarche. Ellis (2004) suggested that the presence of a stepfather in the household would be indicative of unstable parental relations and unreliable resources, thus directing girls toward an accelerated reproductive strategy. A natural extension of this logic would be to compare households in which the mother has a single stable long-term male pair-bond to households in which the mother has a series of short-term pair-bonds (many stepfathers), with presumably one stable stepfather delaying menarche and a series of stepfathers accelerating menarche (Ellis 2004). As yet, this has not been thoroughly examined in the literature. At the core of psychosocial acceleration and parental investment theories is the idea the SFP is stressful (e.g., because of increased conflict or reduced parental investment).

Glucocorticoid levels have been reported to be elevated in children with stepfathers (Flinn and England 1997), and cortisol levels increase near puberty as well (Barra et al. 2015). This is paradoxical, though, as stress is generally viewed as inhibitory on the hypothalamic-pituitary gonadal (HPG) axis because glucocorticoids (stress) disrupt the pulsatile release of GnRH (Whirledge and Cidlowski 2013), unless the relation between stress and the timing of pubertal development is curvilinear as suggested by Ellis (2004).

Another evolutionary approach is to view any putative effect of a stepfather on menarcheal age as being consistent with the “novel male effect” or the “boar effect” (Kirkwood and Hughes 1981; Izard 1983). Essentially, in a wide variety of mammalian species, introduction of a novel male to a social group of female conspecifics can induce an earlier puberty through the stimulatory effect of male pheromones (Colmenares and Gomendio 1988; Izard 1983). In addition to the direct benefits of mating with the new male, it has been suggested that early menarche or displayed signs of estrous in primates may convey a social advantage which would be to obtain the new leader’s support and ascend the social hierarchy. This new alliance would confer an advantage in female-female competition and thus change their social status, ultimately increasing total reproductive output (Colmenares and Gomendio 1988). In addition, maintenance in the natal group of genetically related conspecifics can delay puberty, presumably through pheromonal cues with the evolutionary advantage of preventing inbreeding (French et al. 1984). It has been hypothesized that FA (prevention of inbreeding) and FA-SFP (enhancement of breeding) could both be mediated by pheromonal cues to increase reproductive fitness (Ellis 2004; Matchock and Susman 2006).

In a longitudinal study of 87 FA girls, Ellis and Garber (2000) found that both familial/dyadic stress and stepfather presence (more so than biological father absence) each separately and significantly accounted for earlier pubertal maturation. Moreover, the younger the daughter at the time of the stepfather’s arrival, the earlier the menarche, but only when the mother-stepfather relationship was perceived as stressful by girls. This dose-

response relationship between duration of stepfather exposure and puberty is consistent with greater boar exposure in gilts leading to early puberty (Hughes and Siswadi 1997). In a retrospective study of over 10,000 participants, Quinlan (2003) also found that living with a stepfather was associated with reproductive development, but the duration of the stepfather exposure had no effect. Another longitudinal study of 71 girls also found that stepfather present in the household was a better predictor of earlier puberty than FA alone (Mekos et al. 1992).

Surbey (1990) in her sample of over 1200 girls found that girls with stepfathers present in the home experienced menarche almost two months earlier than FA girls without stepfathers, although this difference was not significant. Alvergne et al. (2008) asked 1200 women to report family composition during age ranges from 0–5, 5–10, and 10–15 years. The FA-SFP-father group had an earlier first sexual intercourse than the FA only group, but only for the 10–15-year time period; age of menarche was not significantly earlier for the FA-SFP group than the FA only group. Sheppard et al. (2014) used a very large, but older, sample of 16,207 participants from the Kinsey survey from 1938 to 1963. FA only and FA-SFP groups were associated with more accelerated life history outcomes than mother-absence households. FA and FA-SFP groups did not differ though. Adopted girls (Proos et al. 1991; Surbey 1990), girls who experience frequent residential relocations (Clutterbuck et al. 2015), and sexually abused girls (Mendle et al. 2016) also tend to have an earlier puberty, both of which are situations associated with putative exposure to unrelated adult males. Finally, the fact that mother-absence girls usually do not experience early puberty (Surbey 1990) would seem to argue against psychosocial and parental investment theories.

However, other studies with relatively large (Bogaert 2005; Matchock and Susman 2006) and small (Hoier 2003) sample sizes have found that having a stepfather in the household did not predict early menarche, independent of father absence alone. Moreover, Mendle et al. (2006) used a genetic “children-of-twins approach” to decouple genetic factors from environmental

factors such as FA and stepfathers. That is, rather than comparing children with stepfathers to an unrelated group of children without stepfathers, the offspring of twin parents discordant for having a stepfather for their children were analyzed. Results indicated that girls raised with stepfathers had menarche approximately 6 months earlier than girls raised without stepfathers. However, when genetic controls were implemented, this effect was significantly attenuated, as the presence of a step-uncle was just as predictive of early menarche as the presence of a stepfather. The offspring of female twins discordant for having a stepfather in the home were equally at risk for early menarche. These data suggest a genetic causal mechanism or perhaps a shared environment confound (e.g., frequent visits by the step-uncle).

Conclusion

Taken together, research suggests that living without a biological father and with a stepfather may be a risk factor for early menarche. The specific biological mechanisms that mediate this relationship have not been fully elucidated yet, nor is there a well-accepted explanatory evolutionary theory. More well-designed studies are needed comparing FA to FA-SFP girls that examine the duration of the stepfather exposure and stepfather-daughter dynamics, including studies that disentangle genetic and environmental factors.

Fear Affords Protection

Vincent Barnett
London, UK

Definition

“Fear affords protection” refers to the evolutionary function of fear as an emotion, which is at root a form of protection or an early warning system

against potentially serious threats. Fear itself has been defined as the “usually unpleasant feeling that arises as a normal response to realistic danger” (Marks 1987, 5). As was explained as early as 1704: “Fear . . . is a disturbance of mind proceeding from an apprehension of an approaching evil, threatening destruction or very great trouble either to us or ours” (Dennis 2000 [1704], 101). In its safe, narrative-generated form (e.g., in terror fiction such as horror novels or films), fear – and the adrenaline rush often associated with it – can become addictive (McCarty 1994, viii). This is because “beside lust and anger . . . [fear is] one of the three most exciting emotions of which our nature is susceptible” (James 1891, 2: 415).

As a very strong emotion, fear serves to alert an animal to any potential dangers, such as from a variety of attacking predators or any looming environmental dangers (e.g., cliff edges or jagged rocks), so as to effectively prepare for rapid action and/or to undertake the required behavior in order to have a better chance of remaining safe (Barrett 2005; Scalise Sugiyama 2006). For example, fear enables various animal response behaviors such as: quickly escaping by the safest route, defense upon imminent attack, freezing if this might assist in predator avoidance, or submitting to an attacker if this may yield a better chance of survival, for example, in intraspecies conflicts (Buss 2004, 91). The protective response of humans freezing in response to the fear generated by an individual suddenly glimpsing “the merciless teeth of Wolves” was noted as far back as the seventeenth century (Brown 1672, 134).

Fear also produces specific physiological and chemical responses, such as epinephrine being released, the heart rate speeding up or slowing down, and increased blood flow to the muscles, all of which assist in the fighting or fleeing behaviors that may be needed in order to survive the approaching danger. As an emotion, fear topped a recent psychologists’ chart of the top ten basic emotions (Parkinson 1994, 488).

Darwin on Fear

Pioneering scientific work on understanding the nature of fear as an emotion, and some associated predatory behaviors, was undertaken by Charles

Darwin. For example, he was particularly interested in “monstrous” or carnivorous plants and conducted his own experiments on how these carnivorous plants absorbed different types of animal flesh as forms of captured prey (Darwin 1875). He also took a stuffed snake to a monkey house in order to test the fear responses of different types of monkey (Darwin 1874 [1871], 72). Darwin was interested in fear as an emotion as part of his wider evolutionary approach to understanding animal behavior.

In *The Descent of Man*, he explained that terror as an emotion caused “the muscles to tremble, the heart to palpitate, the sphincters to be relaxed, and the hair to stand on end” (Darwin 1874 [1871], 69). Although such associations are now sometimes seen as literary clichés, this does not mean that they are entirely inaccurate from a physiological perspective. The physiological changes that are now known to be affected by fear include: blood leaving the digestive tract and rushing to the periphery of the body; the adrenalin level spikes; the heart rate changes, either upwards for fleeing or downwards for freezing; and instruction to various parts of the musculature are sent (Tooby and Cosmides 2005, 54).

In *The Expression of the Emotions in Animals and Man*, Darwin provided a more detailed account: horror was accompanied by the body turning away, or the arms being violently protruded, or the raising of the shoulders, and a shudder and a deep expiration or inspiration (Darwin 1999 [1872], 308). He accounted for the biological function of the physiological reflexes associated with fear and horror as follows:

Some of the signs may be accounted for through the principles of habit, association, and inheritance – such as the wide opening of the mouth and eyes, with upraised eyebrows, so as to see as quickly as possible all around us, and to hear distinctly whatever sound may reach our ears. For we have thus habitually prepared ourselves to discover and encounter any danger . . . Men, during numberless generations, have endeavoured to escape from their enemies or danger by headlong flight, or by violently struggling with them; and such great exertions will have caused the heart to beat rapidly, the breathing to be hurried, the chest to heave . . . And now, whenever the emotion of fear is strongly felt, though it may not lead to any exertion, the same results tend to reappear (Ibid., 308–309).

The underlying principle that was expressed in this paragraph is still valid: the emotions of terror and horror have evolved in direct response to the threats to human life that were represented by animal predators and other human competitors.

Sometime later, in “A Biographical Sketch of an Infant,” he reported that: “*Fear*. – This feeling probably is one of the earliest which is experienced by infants,” as was demonstrated by young children exhibiting startled reactions to any sudden sounds from a very early age, from when they were only a few weeks old (Darwin 1977 [1877], 194). For Darwin, this clearly demonstrated that the fears of young children were independent of learning/experience, and instead were actually instinctual responses to common dangers encountered during the environment of evolutionary adaptedness, or what he called “ancient savage times” (Ibid., 195).

Darwin’s approach to defining the emotions of fear was rather sophisticated, distinguishing between horror and terror/extreme fear by arguing that although horror included terror and was almost synonymous with it, there was an anticipatory and sympathetic element involved with horror that was not present in terror. Terror was thus his term for a fearful emotion that was experienced directly by an individual, whereas horror was the appropriate term for when such terror was either anticipated for oneself, or sympathized with in the case of others (Darwin 1999 [1872], 306).

Darwin’s work on fear was part of his much larger project to understand the evolution of animal instincts, the development of which in its current manifestation is contemporary evolutionary psychology. A much more sophisticated account of the evolutionary basis of fear is consequently now available in the literature on this topic.

Fear as an Evolved Emotional System

Fear has been identified by contemporary neuroscientists as one of the four core premammalian emotional systems, as it is present in all vertebrates (Panksepp 2007, 146). As has been

explained, the fear system in animals is “designed to detect danger and produce responses that maximize the probability of surviving” such danger (Campbell 2007, 368). This fear module has various different behavioral, physiological and verbal-cognitive components, and different animals react to the activation of their own specific fear system differently. For example:

Faced by a dog, a cat will bristle its fur. Because it is frightened, it becomes frightening. A butterfly of the Brazilian forests, the *caligo* defends itself by changing itself into the shape of a head of a bird of prey. It arches its body into the shape of a beak, and opens its wings which bear the image of an eye . . . and thus manages to give such a perfect imitation of an owl . . . (Volta 1965, 73).

Horses often respond to fear by bolting (Romanes 1898 [1878], 329). Fear programming and the fear response in animals thus varies by species and also by individual predator.

Moreover, the fear module is “organized around the amygdala, a limbic structure in the medial anterior temporal lobe . . . Its sharing among mammals and its subcortical location suggest that it has an ancient evolutionary origin” (Ohman and Mineka 2001, 486). To be more precise, it is the central nucleus of the amygdala that is primarily involved in the fear response (Carlson 2011, 278). As has been explained in this regard:

The location of the amygdala gives us a clue to the precise nature of its role in processing fear. It has connections to the autonomic nervous system . . . as well as to other brain regions that process sensory input. It’s like a neurological crossroads, the hub of a network of pathways in the brain, a special “rapid response unit,” if you like, primed to act quickly when presented with danger (Winston 2002, 49).

The fact that the amygdala acts so quickly when the fear module is activated indicates clearly that fear is an instinctual response, not a conscious or controllable one. Confirmation that the amygdala is involved in evaluating potential dangers, such as whether to trust unknown individuals or not, is available from people with damage to this region of the brain, who exhibited (on average) greater attribution of trustworthiness to strangers than a control group with no such brain injury (Patel et al. 2007, 50).

As has been outlined, the fear system has four basic characteristic features: (1) it is stimulus-specific, being activated by particular animals or situations, e.g., snakes or the danger of falling debris; (2) it is automatically and immediately stimulated by the relevant situations; (3) as already indicated, it is not under conscious control; (4) it has specific neural circuitry associated with it (Ohman and Mineka 2001).

Regarding the first characteristic, two key factors assist in tailoring fear reactions to specific stimuli. Prepotency is the fact that certain stimuli take the attention and cause more significant reactions in individuals than others, e.g., snakes and spiders cause much stronger fearful reactions in human beings than flies or birds. Preparedness is the fact that specific responses are tailored to specific stimuli, e.g., human beings exhibit a fearful reaction to snakes but a nauseated reaction to rotting food (Rossano 2003, 170–172).

The fact that this type of fear reaction is instinctive and generated by psychological mechanisms that have evolved in relation to the most common dangers found in the environment of evolutionary adaptedness is indicated by the fact that most human beings still exhibit a fear of snakes and spiders, which are in many contemporary urban environments only a very small danger, but exhibit no fear whatsoever of cigarettes and alcohol, two of the biggest killers of contemporary human beings across the globe.

Not only are specific fears tailored to specific stimuli, the developmental appearance of different fears in the human child progresses according to a well-designed pattern:

The emergence of certain fears, such as fear of strangers (stranger anxiety), fear of separation from a caregiver (separation anxiety), fear of heights, and fear of collision, all show consistent patterns based on the physical maturation of the infant . . . For example, the first evidence of stranger anxiety can be found in 4–5-month-olds in the form of a delayed negative reaction to the prolonged presence of a strange face (Rossano 2003, 173).

In addition, there is also an important place for environmental interaction/influence in the developmental appearance of fear, or what is termed social referencing, with infants responding to their

own unique environmental experiences by showing modified expressions of particular fears, as is appropriate to their own particular environments.

Finally, it has been observed that not only do prey experience intense fear when they are under direct attack from predators, but some predators also experience some degree of fear when attempting to capture some types of prey. For example, when very powerful prey animals are being attacked, which usually occurs only in exceptional circumstances, the attacking predator animal also experiences fear, as they themselves are in some degree of danger too (Curio 1976, 123). As William James noted, “*Fear* is a reaction aroused by the same objects that arouse ferocity . . . We both fear, and wish to kill, anything that may kill us” (James 1891, 2: 415).

Sex Differences in Fear Behavior

There is a general consensus in the literature that there is a degree of difference in how males and females behave with respect to fear, with women (on average over large numbers of individuals) generally experiencing fear somewhat more intensely, more frequently, and for longer durations than men (Campbell 2007, 368), although this is true in relative terms only. Men can still experience very intense fear, given the right circumstances of danger, just as women can. It is probably accurate to state that men and women can experience the same overall range of fear, but that the fear system in men appears to be (on average) set at a little less sensitively than the fear system in women.

This sex difference in fear response is partly confirmed by the fact that, physiologically, it has been reported that women exhibit higher rises in skin conductance and a heightened startle reflex in reaction to scenes of danger compared to men, and that women tend to exhibit greater degrees of phobic fear (Campbell 2007, 369). It has been suggested that this sex difference in fear sensitivity is linked to the fact that males tend to take more risks in general terms than females, for example, in relation to engaging in physical altercations with other members of the same sex. Males also

tend to take more risks (on average) compared to females in relation to their degree of involvement in other physically risky activities, e.g., extreme sports participation and vehicular driving styles.

Malfunctions of The Fear System

The fear system in human beings, however, has some significant in-built flaws that can have important consequences for understanding aspects of contemporary human behavior. For example:

Because self-protection is imperative from an evolutionary perspective, the mind is designed to be hyper-sensitive to threats, even if such threats are ambiguous or hypothetical, similar to how a sensitive smoke detector detects and acts upon the tiniest bit of evidence indicating potential danger at the cost of occasional false alarms (Griskevicius et al. 2012, 315).

The logic at work here is that it is better to set the activation of the protective fear system threat level very low, even with the potential for many false alarms, rather than to fix it at too high a setting, the latter enabling the potential for some genuine threats to go unnoticed.

However, this may mean that some human beings are potentially liable to certain afflictions/malfunctions of the fear system, such as anxiety attacks, vertigo, and various different phobias (e.g., arachnophobia, agoraphobia, claustrophobia), which, instead of assisting the individual to function well, may actually hinder their normal operation in certain very specific circumstances (Marks and Nesse 1994). From an evolutionary perspective, potential malfunctions of the fear system are unavoidable costs that have to be borne, given the overall positive benefit that this system generates for human survival prospects in assorted dangerous environments.

Fear and Intergroup Prejudice

It has been suggested that certain types of intergroup prejudice can be traced to the existence of coalitional psychology as it evolved in relation

to the tribal prehistory of human beings, to associated intertribal conflicts, and to the evolution of in-group out-group fears that were based on the existence of various outsider threats (Park 2012, 188; Kurzban and Neuberg 2005, 667). The related concepts of inclusive fitness and ethnic kinship further suggest that ethnic-nepotism was, in evolutionary times, sometimes a form of adaptive behavior, as it served a useful protective function (Salter 2007, 541).

Tribal conflicts and intergroup hostilities were, therefore, an unavoidable part of human prehistory, and it seems likely that specific psychological mechanisms evolved to deal with these realities. These hypotheses lead to the conclusion that fear, as an evolved emotional system of protection against outsider threats, might be at the root of at least some of the contemporary manifestations of intergroup prejudice. Correctly recognizing the evolutionary roots of this type of fear, therefore, has the potential for better understanding the nature of intergroup prejudice and, in turn, devising better/more effective methods of dealing with it.

Critics of evolutionary psychology may argue that, by positing the existence of this evolutionary basis for in-group out-group prejudice and also for ethnic nepotism, the results can be the justification of such prejudice. These critics need to understand that, if the framework of evolutionary psychology is correct, then ignoring or denying the reality of evolved human nature will not assist in overcoming prejudice. It is much more effective to work alongside human nature in order to solve contemporary problems rather than to work against it or to deny that human nature exists at all.

Fear in Art and Literature

Although of very ancient animal origin, fear is still very much a contemporary emotional reality, one indication of this being the ongoing popularity of the horror *genre* in film and literature across the world (Barnett 2018). If fictive fears in the horror *genre* experienced indirectly – through art and literature – are seen to reflect the

terrors of dangerous splits in the social realm, then real-life fears experienced directly can be seen to reflect the terrors of dangerous splits in the natural world, primarily that between predator and prey (Moretti 2005 [1978], 83; Scalise Sugiyama 2006). These two worlds of art and nature sometimes overlap, providing a further enabling of the protective function of fear.

Consider the example of the werewolf, the mythology of which is “anciently and universally diffused” across Europe and elsewhere, going back at least as far as the thirteenth century (Summers 1934, 20). For Darwin, the transformative power of wolves was not an entirely fictitious quality; he noted reports that a few wolves varied the color-shading on their fur in order to match seasonal changes in the environment (Darwin 1874 [1871], 542). Some human tribes even wore wolf-skins as a symbolic attempt to harness their animalistic powers, and this practice of making hunting disguises from animal skins has been cited as the origin of the werewolf mythology (Langford 1997, 1006; Stewart 1909, 260).

The historian of occult mythology Montague Summers, known for his belief in the reality of supernatural creatures like vampires and werewolves, unknowingly described very clearly how natural predators like wolves readily assumed a larger-than-life quality in the ancestral human consciousness:

Throughout the ages, even in the prehistoric world, whilst his howling athwart the stillness of nature and night struck fear into the heart of primaeval man . . . further down the centuries when he was known as the savage plunderer and swift pitiless marauder of the shepherd’s grazing flocks, not sparing to attack child and maid or even the solitary wayfarer by the wood . . . all down the vistas of dateless centuries the wolf has ever been the inevitable, remorseless enemy of man . . . [part of] the experience and dearly purchased knowledge of our forefathers . . . (Summers 1934, 64–65).

Summers’ error was in taking the mythologized version of the wolf too literally, when what should have been taken literally, was the folk-narratives that have been used to warn of the real dangers of wolf attacks: “as the flesh-and-blood wolf continues to haunt the Transylvanian forests, so long will his spectre brother survive” (Gerard 1888, 187).

The link between superstitions expressed in nightmares and the “sudden transformation of one person into another or into some animal; the occurrence of phantastic and impossible animal forms” has previously been highlighted (Jones 1931, 238). This fearful link makes concrete the connection between primitive animal dangers and modern horror narratives that allude to the animal side of human nature and related transformative themes, which in reality are simply mediated embellishments on much older predator fears.

Conclusion

Beginning with Darwin’s pioneering work on understanding fear, evolutionary psychologists have more recently given the protective function of fear their full investigative attention, as it is a powerful and an important emotion that affects many different aspects of human behavior, most importantly, assisting the survival instincts. Consequently, instead of the false promise of the anemic adage “nothing to fear but fear itself,” the much more realistic maxim that animals live by is “nothing to fear but the many thousands of predators spread across the globe.” From a Darwinian perspective, fear is not a “mind killer” that has no real rational foundations, as has been argued elsewhere (Plamper and Lazier 2012), but instead is an essential “mind saver” that all animal life constantly relies upon for its ongoing survival.

However, various malfunctions of the fear system are also important to understand as they may be at the root of the prevalence of various contemporary panic and anxiety disorders. In addition, only by understanding the evolutionary origins of fear as an emotion, will any potentially negative side effects of it that are still being manifest today, such as intergroup prejudice, be able to be effectively mitigated. Finally, it should be stressed that human beings should not be frightened of expressions of fear but instead should celebrate and revel in them, as such frightful and terrific expressions of emotion have undoubtedly contributed to saving countless human and animal lives across the vast evolutionary past.

Definition

Real or imagined objects or situations that elicit psychological, physiological, biomedical, and behavioral responses to protect an organism against perceived danger or threat.

Introduction

In Isaac Marks' [1987](#) book *Fears, Phobias, and Rituals: Panic, Anxiety, and Their Disorders*, he described fear as an emotion produced following the perception of present or impending danger that leads an organism to avoid threat, has obvious survival value, and is normal in appropriate situations (Marks [1987](#)). Fear reactions exist in

humans and across animal species to protect or defend against present or anticipated threats in the environment. Fear is characterized by a number of psychological and physiological reactions and biomedical changes, occurring simultaneously or sequentially. These include visible behavioral expressions, such as freezing or fleeing, and accompanying psychological and physiological changes, such as feelings of terror, crying, a pounding heart, nausea, and an urge to run and hide. Finally, biomedical changes associated with fear include the secretion of both adrenalin and noradrenalin at the peripheral nerve ending of the autonomic nervous system. Marks suggested that some aspects of what we fear and how we express it are biologically determined, while others are affected by our individual and group experiences. Examining the development and acquisition of fears has been the focus of extensive research, as researchers have struggled to explain individual differences regarding if, when, and how both evolutionarily relevant and nonrelevant fears are formed.

Conditioning Theory of Fear Acquisition

Fears are assumed to be acquired and the process of acquisition is a form of conditioning. Fear conditioning is similar to classic conditioning pioneered by Pavlov ([1927](#)), but pairs the conditioned stimulus with an intrinsically noxious or harmful unconditioned stimulus to elicit species-typical fear responses. Proposed by Eysenck and Rachman ([1965](#)), the conditioning theory of fear acquisition assumes that any stimulus can be transformed into a fear signal. This theory suggests that given similar frequency and intensity of exposure, all stimuli should have nearly an equal chance of being transformed into fear signals. It also states that the strength of the fear is determined by intensity of the experience in addition to the number of repetitions of the association between the painful or frightening experience and the stimuli. Finally, the theory suggests that the likelihood of fear developing is increased by factors such as exposure to high-intensity pain and/or fear experiences and by frequent repetition

of the novel association between the stimulus and the pain or fear. One of the most famous studies of fear conditioning was conducted by Watson and Rayner (1920), who conditioned fear of a white laboratory rat in a young infant referred to as “Albert” by pairing the presentation of the rat with a loud and frightening noise. They also observed that Albert’s conditioned fear generalized to similar furry stimuli, such as a rabbit and furry dog, consistent with the conditioning theory’s claim that stimuli resembling the fear-evoking ones also acquire fearful properties. However, Rachman (1977) noted that researchers had mixed results when testing Watson and Rayner’s finding and presented several arguments against the conditioning theory of fear acquisition. These included the failure of people to acquire fears in fear-evoking situations, difficulties producing conditioned fear reactions in humans, and evidence against the premise that any two stimuli can be associated with each other with equal ease. Therefore, Rachman proposed a three-pathway model of fear acquisition.

The Three-Pathway Model

While Rachman (1977) acknowledged that direct conditioning remained an important fear-induction process, he proposed that at least two other pathways could be identified, distinguished by being indirect processes of acquisition, and integrated into a single model. The first is the vicarious acquisition of fears, where humans and animals can acquire fear of a stimulus (animal, object, or situation) by witnessing another individual’s fear of it. Based on observational learning, Rachman suggested that fears could be acquired directly or vicariously and that neutral stimuli would likely acquire fearful qualities if they were directly or vicariously associated with painful or frightening experiences. The ability to appropriately detect and respond to signs of fear and pain in a member from the same species likely conferred an important selective advantage during evolution. In addition to alerting the receiver about potential imminent danger, they also assign a threat value to the

context or cue associated with the threat (Olsson and Phelps 2007). A recent review of cross species research on vicarious fear learning, also referred to as social fear learning, by Askew and Field (2008) supports the claim that this pathway plays an important role in the development of many fears. However, researchers also agree that vicarious learning is likely a form of conditioning and that experiencing an aversive episode vicariously may not in itself be sufficient to predict fear acquisition.

The second pathway proposed by Rachman was fear acquisition by the transmission of information and/or instruction. He remarked that information giving is an inherent part of raising a child, carried out continuously by parents and peers during the child’s earliest years, and is likely the basis for the most commonly encountered fears of everyday life. However, fears acquired in this way are more likely to be mild rather than severe. Rachman proposed that an advantage of these two additional pathways was that unlike conditioning, they could account for the fact that people display fears of situations and objects which they have never encountered. He suggested that accepting that fears can be acquired by informational processes allows us to explain some, but not all, of the failures to acquire fear in situations where it might have been expected to occur based on the conditioning theory. That is because information and instruction also help humans and animals to learn to distinguish those situations and objects which are not dangerous and therefore need not be feared.

The Nonassociative Pathway

Decades later, Poulton and Menzies (2002b) proposed a fourth pathway to account for fears that are not acquired by conditioning or other learning processes, for which the three-pathway model struggles to explain. They suggested that the addition of a nonassociative pathway contributes to the understanding of the nonrandom distribution of fears, failures to recall conditioning events in fear onset, and the seemingly paradoxical finding that people with high levels of fear report less

direct traumatic events than those without such fear. Poulton and Menzies claim that a non-associative model of fear acquisition asserts that members of a species, given normal maturational processes and background experiences, will show fear to a set of biologically and evolutionary-relevant stimuli. Evolutionary-relevant fears (e.g., fears of spiders, heights, water, darkness) acquired in this way would have the following features: the feared stimulus must represent a longstanding danger to the species, fear and avoidance of the stimulus must have increased reproductive opportunities in our ancestors, and the fear and avoidance of this stimulus is partly under genetic control. Therefore, this pathway enables researchers to account for fears with an evolutionary background appearing without any relevant direct or indirect associative learning experiences. Evidence for the nonassociative model has largely come from the findings of retrospective and longitudinal cohort studies, which suggest that relevant associative learning experiences had not occurred based on recall by phobic individuals. Critics of this model highlighted methodological problems with these studies, such as the unreliability of retrospective recall, especially when it is generally many years after the alleged experience took place (Mineka and Öhman 2002). However, Poulton and Menzies (2002a) maintained that an expanded four-pathway model offers the most inclusive, comprehensive, and parsimonious theoretical account of fear acquisition that integrates diverse findings from multiple disciplines.

Conclusion

Fears are crucial to the survival and well-being of humans and animals, allowing organisms to avoid threat, react to danger, and enhance performance. Fear is a package of reactions, occurring simultaneously or sequentially, resulting in psychological, physiological, biomedical, and behavioral changes. Theoretical models of how fears are acquired have changed, starting with a direct conditioning theory of fear acquisition, to a three-pathway model that includes indirect acquisition

pathways, and finally to a four-pathway model to incorporate a nonassociative pathway of fear acquisition. This comprehensive model of how fears are acquired is crucial in order to understand the development and treatment of maladaptive fear such as anxiety and phobias.

Definition

Fear is a normal emotional response to actual danger; it motivates individuals to either avoid the danger or to elicit adaptive species-specific defense behaviors, which reduces threat to life or general harm or loss. Phobias are exaggerated fear responses to specific stimuli that are not really as hazardous as the response suggests, and the avoidance and safety behaviors patients engaged in are maladaptive or unnecessary and often the maintaining feature of the disorder.

Introduction

Every living thing intuitively responds to threat. Fear, a quick and normal emotional response to danger, motivates species-specific defense behaviors, such as the fight-or-flight response. Fears are considered rational, appropriate when such defense or avoidance behaviors are elicited in response to a definite danger; as such, the function of fear is to avoid harm or death. Anxiety is an inappropriate or irrational fear response triggered in the absence of actual danger. Exaggerated, irrational, and extreme manifestations of fear or disgust and avoidance of specific stimuli in the absence of proportional danger are considered specific phobias.

Anxiety disorders are highly prevalent in the population, afflicting approximately 18% of the U.S. adult population in any given year. For females, lifetime and past-year rates of anxiety disorders are 1.5–2 times higher than in males, a trend that is mirrored in the domain of specific phobias.

Few areas of mental disorders have been as clearly influenced by functional and evolutionary thinking as anxiety. Almost all anxiety researchers and clinicians accept the idea that normal, adaptive fear functions as a signal that triggers appropriate defensive response. Because anxiety constitutes an exaggerated, maladaptive response despite there being no objective, present danger, and because persistent attempts to remove such nonexistent threat contribute to its maintenance, it is generally considered maladaptive. Even if a stimulus involved mild discomfort or pain (e.g., wasps and injections), the fear or disgust response may be considered exaggerated compared to actual pain or danger. This includes the avoidance that may reduce general function, well-being, or health benefits.

Evolutionary Accounts

Considering the phenomena people in general are most phobic of quickly reveals a list of possibly evolutionary relevant phenomena: heights, dark, strangers, small and large animals (and especially snakes and spiders), and open and closed spaces. Since none of these ancestral hazards are specifically dangerous today, evolutionary accounts of preparedness therefore ring true for most clinicians (Kennair 2007; Marks and Nesse 1994; Öhman and Mineka 2001). Further, governmental health and safety campaigns often attempt to instill fear toward specific stimuli, yet they commonly fail to do so. This is due to the hedonic valence of the stimuli, making our approach behavior to harmful stimuli (e.g., fat, sugar, speeding, drugs including nicotine and alcohol, unprotected sex, and speeding) problematic. Our desire to enjoy these things so much overrides their fear-inducing potential, to an extent that they through their availability present a challenge

to our health in a modern, evolutionary mismatched ecology – even if they were not dangers in the EEA.

Acquisition of Phobias

For many decades, phobias were considered a result of conditioning. According to Mowrer's behaviorist theory (Mowrer 1947), two types of conditioning were involved: first, classical conditioning, i.e., being stung by wasp, and, second, operant avoidance, e.g., avoiding a room with a wasp in it. However, many stimuli do not provide a basis for classical conditioning, and one often finds that those who have been stung are less phobic than those who avoid wasps due to their phobia. Model learning has also been offered as an explanation, but this only moves the explanation of phobia acquisition back a generation or more. The limitations of associative pathways were recognized early by anxiety researchers (Rachman 1977), and experimental research has challenged the generalizability learning or equipotentiality of stimuli (Seligman 1970; Öhman et al. 1976). Work by Öhman and Mineka (2001) considered how humans are prepared to fear specific stimuli. The recent years have seen an increased focus on non-associative pathways, championed by the longitudinal work of Poulton, Menzies, and colleagues (Poulton and Menzies 2002a, b). Recently, Sandseter and Kennair (2011) suggested that childrens' tendency to engage in risky play might constitute a mechanism that reduces naturally maturing and occurring fears of ecologically relevant threats coinciding with the development of psychophysical and motor skills, thereby promoting approach and reducing safety behaviors. The mode of acquisition of phobias continues to be addressed from an evolutionary perspective (Hoehl and Pauen 2017).

Recent Evolutionary Developments

Recent evolutionary research is still inspired by the pioneering work of, e.g., Öhman and

colleagues. Certain fears and phobias occur naturally during different stages of human development (e.g., separation anxiety and fear of heights) that follow a complex, yet stable, pattern (Boyer and Bergstrom 2011). Employing visual detection paradigms, recent developmental work has demonstrated that visual attention in infants and young children is prioritized for potentially dangerous stimuli resembling ancestral hazards, well before they acquire any threat-relevant fears. Others show that infants readily associate snakes with fear (DeLoache and LoBue 2009) and are quicker to detect the presence of spiders than various categories of biological distracter stimuli (LoBue 2010). Using a preferential looking and habituation paradigm, Rakison and Derringer (2008) demonstrated a perceptual template for spiders that generalizes to real-world images of spiders, but not for other nonthreatening biological stimuli in infants as young as 5 months old. These findings are in line with studies that show that other arthropods (e.g., bees/wasps) are not perceived as threatening as spiders (Gerdes et al. 2009; New and German 2015).

Other studies show that these threat-detection mechanisms are maintained in adults. Jackson and Calvillo (2013), for instance, demonstrated that participants completing a visual search task located evolutionarily relevant and animate objects fastest and with the least impact of high perceptual load, compared to evolutionarily novel and inanimate objects. Further evidence stems from research on an unusual but common phobia, trypophobia, in which images of holes instill fear. Conducting a spectral analysis on a variety of images that induce trypophobia, Cole and Wilkins (2013) found that fear-inducing stimuli had a spectral composition typically associated with a range of potentially dangerous animals. Kazanas and Altarriba (2017) demonstrated memory advantages for unknown (supernatural) predators. Overall, these findings echo evidence that animate objects are mirrored more closely than inanimate objects, independent of considerations about which pose more serious threats in modern environments.

In an original approach to the evolution of phobia, Miloyan et al. (2016) suggest that for

humans, specific phobias demand a capacity for mental time travel. This may account for the chronicity of this disorder, as actual dangers in the EEA would need to be avoided consistently and over long periods of time, including mechanisms of planned avoidance.

The Special Case of Blood Injury Injection Phobia

The special case of blood injury injection phobia, the only anxiety disorder that leads to fainting of those affected, illustrates the adaptationist evolutionary approach to danger – an actual danger is countered by a relevant adaptive response. Rather than increasing adrenalin and activation, there is a fall of blood pressure, which might be the most adaptive response to severe blood loss (Kennair 2007; Marks 1988).

Treatment

Despite the fact that phobias are not necessarily acquired through associative pathways such as conditioning, behavioral therapy – exposure therapy including response prevention – constitutes the most efficient treatment of phobias. In general, it seems that reducing avoidance and discontinuing safety behaviors lead to a decrease in anxiety levels. The idea that evolved mechanisms are malleable and that learning is an evolved function, which better makes us better adapted to our environment, is not at odds with an evolutionary perspective.

Conclusion

Generally, evolutionary clinical psychology has had little influence on mainstream mental health care. Most anxiety therapists will use evolutionary perspectives in psychoeducation, to explain the patients' exaggerated responses and, in so doing, normalize these. The obvious exception is treatment of anxiety in general and phobias

specifically. Beyond the understanding of the function of fear and safety behaviors, evolutionary perspectives have informed our understanding of predispositions to fear specific stimuli and how phobias and anxiety may mature through non-associative pathways. Recent work continues a tradition of considering specific evolutionary relevant stimuli and the evolved mental mechanisms designed to perceive these.

Feeding

Stephen R. Merritt
University of Alabama at Birmingham,
Birmingham, AL, USA

Synonyms

[Consumption](#); [Eating](#); [Provisioning](#)

Definition

Consumption of edible resources in order to sustain an organism’s energetic and nutritional demands.

Introduction

All heterotrophic organisms feed on other life; therefore, feeding is fundamentally an interaction between consumer and the consumed, and its relationships to surrounding contexts can be informative. Feeding is ecological, where agents like predator and prey interact within physical, biotic, and perhaps social contexts and exchange energy inside ecosystems. For humans, feeding intersects with our social worlds, and our foodways – the cultures surrounding food – are enmeshed in biocultural feedback loops.

Feeding is essential to offspring development, particularly in humans where parental investment sustains young individuals as they develop and grow, and values and social norms are enculturated via foodways.

This entry discusses evidence from the human fossil record, archaeological traces of feeding, and behavioral ecological data from extant nonhuman primates and humans practicing diverse subsistence strategies to investigate how the evolutionary history of human feeding and dietary ecology may underlie adaptations that define humanity, notably our cognitive abilities, long childhoods, reliance on technology, and our extreme sociality.

Bento Boxes: A Contemporary Example of Enculturation Through Food

In Japan, bento or lunch boxes full of creatively prepared and neatly organized food items prepared by mothers accompany young children as they begin nursery school, leaving the comfort of home and beginning an important journey of cultural development. Allison's (2013) ethnographic account shows bento's role as ideological state apparatus. In other words, the lunch box itself, but also the contexts surrounding its preparation and its consumption at school, functions to reinforce cultural values. In this case, mothers' food preparation reifies gendered social roles, and other cultural values like discipline and obedience to authority are reflected in the social pressures that guide mothers' bento preparation. Proper bento should attract children with interesting and cute shapes, prompting them to quickly eat their lunch.

This behavior is reinforced by teachers who monitor the classroom and encourage proper eating behavior to instill the discipline necessary for the child's future schooling – where success is crucial for their adult employment.

A Biocultural View of Feeding and Human Life History

The previous example shows how western, industrialized ideology is delivered through food and how the biological necessity to eat is enmeshed in a cultural context. The diversity of human foodways is vast, and examining the interaction of feeding culture and biology provides an interesting analytical perspective to address important questions in human life history like why, compared to other mammals and primates, we have long childhoods and live a long time, including a long post-reproductive period (Crittenden et al. 2013). Further, males and females face different energetic trade-offs related to gestation, and parental investment via nursing and other provisioning, and address these needs with the help of complex cultural mechanisms. Although diversity in human mating systems is wide-ranging, pair-bonding (sometimes serial in nature) and allo-parenting along with other means of offsetting costs of childrearing through kin networks are unusual in the primates, but common in many human groups.

Additionally, maternal and paternal investment differ; parents provision their offspring indirectly during gestation and during their juvenile phase while nursing and, as they wean, introduce children to adult foods and teach them to support themselves. Here it is informative to examine trends in human groups across a variety of cultures that engage different subsistence strategies (i.e., foraging, horticulture, industrial agro-capitalism, etc.). A study of nursing behavior and parental investment in 58 cultural groups found that on average humans wean their infants at 2.5 years, which is earlier than expected for primates given dental developmental markers and life history variables like adult size. This suggests weaning age "may be at an adaptive minimum; hence in many

environments the challenge is not to find ways to reduce lactation, but rather to extend it” (Quinlan and Quinlan 2008, p. 89). After considering a host of variables, they find that alloparenting and divorce prevalence most strongly predict early weaning, suggesting that conjugal stability is related to delayed weaning cross-culturally, but social networks surrounding nursing mothers also impact the length of nursing. Further, because lactation may suppress reproductive cycling and limit reproductive success, a shorter nursing period may reflect selection for a shorter inter-birth interval that improves individual reproductive success and may underlie human population growth (Kennedy 2005).

Like chimps and some other tool-using animals, juvenile humans learn technologies to feed themselves through social interaction, not only from elders but by playing with kin and age mates (Horner et al. 2006). For children living in the contemporary industrial world, food is mediated by parents or caretakers with access to capital, but foraging juveniles are provisioned as they are weaning and quickly begin to accumulate a large portion of their daily caloric needs on their own, often targeting resources appropriate for their size (Lew-Levy et al. 2017).

Evidence from the Fossil Record

The fossil record of human evolution provides evidence to address the intersection of life history and feeding in earlier human taxa, but these data are typically rare and often incomplete. However, with careful interpretation, conclusions about human prehistory serve as important signposts that document humanity’s evolving physical, behavioral, and cultural adaptations at points in time and space.

Tool-assisted feeding is not restricted to humans. Chimps modify objects to create tools for extractive foraging, but human tool use is complex and involves greater movement of material across landscapes compared to other animals. Controversial marks on fossil bone at Dikika, Ethiopia (3.4 million years ago) may reveal evidence of the earliest known butchery of animals with unmodified stone to access marrow and other

within-bone nutrients. Once the archaeological record begins to offer clear evidence of tool-assisted carnivory, abundant evidence shows that early genus *Homo* is flaking stone and using it to butcher a variety of animals from monkeys to hippos (Ferraro et al. 2013). The introduction of animal foods (and aquatic foods) may have played an important role in dietary changes which underlie evolution of increasing brain size, but this conclusion should be considered alongside the facts that plant foods and other dietary items are less visible in the fossil record and many paleoecological inferences about ancient feeding behavior cannot be addressed because of the resolution of the archaeological record. Therefore, a more robust conclusion from the fossil record recognizes that the human diet has evolved to its current state through technological and social adaptations. The increasingly complex technological innovation that characterizes human evolution often focused on feeding adaptations, from the use of tools to butcher animals, to projectile hunting technology, and plant and animal domestication, and throughout, these changes in subsistence involved social transmission of knowledge.

Despite the fact that much of prehistory people learned about their foodways and associated technology socially, evidence of social transmission of technological knowledge between individuals is hard to find. For example, the archaeological record is often too coarse to discern children’s tool-making (Shea 2006). However, fossil skeletal material provides evidence to assess certain aspects of diet across the lifespan and therefore understand more about how feeding and life history were interwoven in prehistory. In particular, enamel hypoplasia, or disruptions in enamel formation during tooth crown formation caused by metabolic stresses or dietary changes, provides a useful tool for understanding how feeding and life history intersect in an individual (Smith 2013).

Interpreting growth in fossil taxa is possible by identifying the neonatal line and counting daily enamel deposits, providing a high-resolution age estimate. However, age estimates lose resolution after dental growth ceases because age-related skeletal degeneration and tooth wear provide much less precise reconstructions of the later phases of hominin

life history. Further, comparing patterns of growth in fossil humans suggests that the prolonged childhood and exaggerated life history that characterize *Homo sapiens* may have occurred to a lesser degree in relatively recent taxa like *H. heidelbergensis* and the Neanderthals.

Austin et al. (2013) developed a new method for measuring the barium distribution across developing teeth that captures evidence of dietary changes during early life history. Using a living macaque experimental model and data from human infants, they trace changes in barium levels in the womb where it is blocked by the placenta, through birth and the onset of nursing where barium is enriched, and the subsequent drops in barium that occur when nursing is supplemented with solid food and when it ceases entirely. Applying this method to a juvenile Neanderthal tooth from Scladina, Belgium, dated to 80–127,000 years ago, indicated that as expected the 8-year-old child grew relatively quicker than *Homo sapiens*. Prenatal enamel formation lasted 13 days before barium increased with the exclusive consumption of milk for around 7.5 months. Afterward, intermediate levels suggest supplemental provisioning with solid food until about 1.2 years when barium levels dropped significantly with the abrupt cessation of nursing. Although the life history of this Neanderthal child appeared quicker than modern humans, meaning it achieved dental developmental markers at a relatively earlier age, its weaning age fits inside with the normal range that surrounds the human average of 1–4 years. Continuing dental development showed that this child lived beyond tooth formation, but we have no evidence to reconstruct its diet or how it changed later in life. We don't know whether weaning was initiated by a younger sibling's appearance, the mother's disappearance, the beginning of adult-like foraging behavior, or some other reason.

Typically, diet is reconstructed in human fossils by analyzing carbon and nitrogen isotopes in teeth but this only offers a blurred glimpse at the trophic position (i.e., relative animal versus plant foods) and the overall consumption of woody or grassy plant foods. Further, these methods only record dietary preferences during tooth formation, which occurs early in life. In contrast, dental

microwear analysis, which can discriminate certain food items mainly by their texture and hardness, offers a snapshot of which foods were consumed during adult life, but only for the final 2 weeks before death when tooth wear is not overprinted. Unfortunately, these methods provide sophisticated ways to address feeding ecology in fossil human taxa, but do not provide a longitudinal view of diet throughout the complete life course, and often stand as the only sample of dietary ecology for an entire fossil species or period of time.

Still, single specimens provide intriguing evidence of the prehistory of another prevalent human social behavior – care for the sick or elderly. The Iraqi Neanderthal skeleton Shanidar 1 (35–45 thousand years old) was likely blind and deaf and carried a healed, amputated arm. Because foraging in this condition would be difficult, this specimen arguably represents an early prehistoric instance of care of sick or incapacitated group members. The deep roots of care for elderly individuals may go back even further if the edentulous *Homo erectus* cranium from Dmanisi, Georgia (1.8 million years ago), is correctly interpreted as a long-lived individual who may have been provisioned by other group members.

Conclusion

Feeding behavior is complex in living people. We are omnivorous, social, and technological, and these flexible adaptations contribute to significant diversity in human foodways. Even if the dietary items or specific foraging behaviors cannot be precisely reconstructed throughout most of the human evolutionary record, individuals not only feed themselves but also provision offspring and may be fed by others as they age, highlighting the biocultural nature of our diet and its intersection with life history stages. Selection pressures that favored a slower human life history and lengthened childhood in *Homo sapiens*, providing a time where individuals socially acquire skills and are enculturated with the tools necessary to live, including how to feed themselves. This life history trend appears in earlier members of our

genus and has co-evolved with the other unique human traits like increased brain size, cultural complexity, and technological sophistication.

Definition

A coalition is defined as an aggressive attack of two or more individuals against one or more targets. Most frequently coalitions involve two individuals aggressing against a common target. Coalitions are prevalent throughout the animal kingdom and their frequency between males is surprising as males are most frequently the

dispersing sex and thus there should be no kin-related benefits of cooperation. The formation of a coalition can be opportunistic whereby one individual joins one of two individuals during a dyadic aggression. Coalitions can be very basic and involve no communication between the coalition partners and an individual purely intervenes in an on-going aggression. Alternatively, coalitions can be coordinated attacks with individuals aggressing against a common target with similar forms of aggression and movement. These aggressions can involve recruitment of specific individuals from a population or social group. Individuals can use specific behaviors and vocalizations to recruit their partner and the aggression often appears to occur spontaneously between the coalition partners.

Introduction

In the animal kingdom coalitions have been observed among many taxa from birds to cetaceans to social carnivores and ancestral human species. Coalitions are most frequently observed in nonhuman primate species and occur under a variety of circumstances and constellations described below (reviewed in; Smith et al. 2010).

Many different functions can be provided by coalitions including defense of or access to resources, rise in rank position for one or both partners, defense against aggression from a more dominant individual or defense against group take-overs from rivals (reviewed in Harcourt and de Waal 1992; Olson and Blumstein 2009; Smith et al. 2010). Nepotism and kin-related benefits of cooperating and supporting relatives are considered to be the main drivers behind coalitions between group-living females (Isbell 1991; Sterck et al. 1997; van Schaik 1989; Wrangham 1980). In the majority of primate species, males are the dispersing sex, and therefore move from their natal group at maturity. They are without kin or may not recognize kin in their new group but coalition formation is still often seen. Coalitions can either be between individuals within the same group (within-group coalitions) or individuals of one social group join together to fight against

another group of individuals of another social group (between-group coalitions).

Within-Group Coalitions

Gregarious male primates compete for access to mates within their social groups, and in many primate species males can use within-group coalitions to gain access to females. This form of cooperation is intriguing as under such circumstances males are competing for access to a non-divisible resource (access to females) and so cooperation should be unlikely. Recently a mathematical model has been developed to explain the evolution of different male-male coalition types within groups (Pandit and van Schaik 2003; van Schaik et al. 2004, 2006; also see Young et al. 2014b; for a review of alternative coalitionary models see Bissonnette et al. 2015). These models predict when certain coalition constellations and types are likely to occur within social groups. The model assesses the profitability (the coalition must provide fitness benefits for the partners) and feasibility (the coalition partners must be able to defeat the target) of certain coalitions occurring at different levels of contest competition within groups. Contest competition is based on the level with which the alpha male can monopolize mating access to females. Coalitions can be classified into three constellations based on the ranks of the allies (coalition partners) and target in the coalition: (1) *all-up*, where both allies are lower ranking than the target, (2) *all-down*, where both allies are higher ranking than the target, and (3) *bridging*, where the target is ranked between the allies. These coalition constellations were further categorized into types by their function, being either “*rank-changing*” when they affect participants’ rank position, or “*levelling*,” when they reduce the inequality in the distribution of matings/paternities across ranks. Rank-changing coalitions are also known as “political” or “revolutionary” coalitions. One of the main assumptions of the model is that payoffs for the coalition partners are mediated by dominance rank rather than male fighting abilities.

Contest potential within groups' ranges from very high (where the alpha male has complete monopoly of mating access) to very low (where all males can mate with females and scramble competition occurs). In species with very high contest potential, coalitions are not expected between males as mating access is highly skewed to the alpha male. There are often few subordinate males and the high contest leads to large power differentials between males, hence, coalitions become unfeasible. Conversely, if contest potential is extremely low, then scramble competition is likely to develop and all males in the group can gain access to females and thus cooperation provides costs but no benefits to the allies. The mathematical models, therefore, predict that male-male coalition formation should occur from high to medium levels of contest potential but not at the extremes. The models further predict the coalition constellations which will occur at differing contest potential, these are outlined below.

Levelling coalitions become feasible as contest competition begins to decrease to a mid-high level as males can gain benefits from cooperation, which were not possible at extremely high contest. Here males can cooperate opportunistically to gain access to receptive females, by breaking up a consortship between a male and female dyad: as has been observed in savannah baboons, *Papio cynicephalus* (Bercovitch 1988; Noë and Sluijter 1990, 1995; Packer 1979) and Barbary macaques, *Macaca sylvanus* (Bissonnette et al. 2011). By combining their extrinsic fighting abilities, males are able to reduce mating opportunities of higher ranked rivals, effectively creating a level mating skew for subordinate males. When recruiting a partner, males must weigh-up the available allies and the target to recruit a partner who will provide enough combined intrinsic fighting ability to defeat the target. The undecided nature of the payoff outcome can make the opportunistic coalitions attractive for both partners (Noë 1990) as the highest ranked partner does not always gain access to the female. Both benefit by breaking up the consortship and simultaneously reducing the future mating opportunities of the consorting male and increasing the probability of future mating opportunities for the coalition partners.

Levelling coalitions provide a short-term, opportunistic alternative mating strategy to gain direct benefits in the form of access to consorted females.

Coalition formation is not only beneficial in terms of gaining temporal access to females, and the payoffs to individuals are not only related to immediate benefits of access to the female. Male dominance rank position is highly correlated to reproductive success, thus, attaining high rank position can increase a male's reproductive success. As contest potential decreases further, males can cooperate through rank-changing coalitions to increase the rank position of one or both partners. Rank changes through coalition formation can be achieved with one interaction but may require repeated coalitions afterwards to defend the new rank position and thus partners may need to interact over longer periods than with levelling coalitions. Rank-changing coalitions carry high immediate costs to the participants as higher ranked targets can show counter-aggression, and sexual selection has equipped males with extensive weaponry (e.g., large canines and body size). Recruitment of a coalitionary partner should therefore consider the reliability of the partner previously because if they were to defect (i.e., leave the fight as it is on-going) then their partner would be left in a vulnerable position possibly leading to serious injury during the fight (Ostner and Schülke 2014; Young et al. 2014b). As the rank change occurs with the cooperation of another individual, the intrinsic fighting abilities of those involved remain the same and as a result the partners should continue to form coalitions to defend and cement the newly acquired higher rank position (Ostner and Schülke 2014; van Schaik et al. 2006; Young et al. 2014b).

Regular coalitionary partners can provide further benefits as they can act to increase a males extrinsic power even in the absence of the partner and function to intimidate opponents and reduce the probability of aggression from higher rank individuals (Berghänel et al. 2011). Under such circumstances, male-male social relationships might be the key as the formation of social bonds between group members can help to facilitate this cooperation between individuals.

Repeated affiliation between individuals through social behaviors such as grooming, being in close proximity without aggression or triadic male-infant-male buffering may show a willingness to cooperate and develop strong social bonds between individuals (Ostner and Schülke 2014). A correlation between grooming given and support received has been shown in both male and female primates (Schino and Aureli 2008). This is highlighted in Assamese macaques (*Macaca assamensis*) where male future rank position could be predicted by the frequency with which they formed coalitions and those forming coalitions more often rising in rank in the future (Schülke et al. 2010). Additionally, those males without strong bonds, formed coalitions less frequently and fell in rank. Furthermore, male coalitionary partner choice is related to social bond strength. In Barbary macaques, males recruited the partner with the greatest social bond strength more frequently from the pool of available bystanders when a dyadic aggression occurred. Males were also more likely to fail to recruit a partner if their opponent had a stronger social relationship or was of higher rank to the bystander than between the bystander and the recruiter (Young et al. 2014a). Only a small number of primate species show male-male affiliation, but where affiliation is frequent and social bonds are formed and differentiated, these factors are expected to play a major role in coalitionary partner choice. Although strong social bonds are important for the selection of a reliable partner, rank-changing coalitions have also been observed where male-male affiliation is infrequent or absent. In general, rank-changing coalitions can be considered a more long-term strategy to increase an individuals' position in the dominance hierarchy and lead to long-term reproductive benefits of higher status.

Besides rank-changing and levelling coalitions, the third constellation is bridging coalitions. These coalitions involve a high ranked individual and a subordinate against a target ranked between them. These coalitions are predicted to occur between kins as only by assisting a relative can they remain profitable for the high ranked partner. But they are also observed in species where

individuals show strong male-male social bonding and where individuals have a regular socially bonded partner. For example, if a rank-changing coalition has occurred involving two bonded partners, it may be one partner remains low ranked and the two continue to form coalition's post-rank change to cement the higher individuals' new rank position. As a result these coalitions would then be bridging. A subordinate may support a high-ranked partner against a mid-ranked challenger in order to gain future favor and support. Thus, where males form social bonds and recruit their bonded partner, bridging coalitions are more likely to occur.

Between-Group Coalitions

Besides within-group coalitions, males can form coalitions with members of their own social group against members of another social group (known as between-group coalitions). These usually occur in defense of resources such as feeding sites or females against single males, multiple males, or other groups. These between-group coalitions are common as males cooperate against a common enemy and success leads to a common benefit for those involved defending the resource in question. Currently, a mathematical model predicting their feasibility, constellation, and occurrence is lacking. Additionally, future costs of cooperation can be lower as the target(s) of the aggression will not be in their social group at a later date when possible retaliation could occur. These coalitions are often very large in size compared to within-group coalitions. Males can also use coalitions to takeover a group; for example, an influx of bachelor males can usurp the current alpha male and even other resident males to assume control of the group (Borries 2000). In some instances, male coalitions against neighboring groups and within their own social group can be lethal and either directly or due to the injuries sustained in the aggression lead to the death of the target. In chimpanzees (*Pan troglodytes*), in particular, this behavior has been witnessed many times and has been likened to human warfare. Lethal coalitionary aggression is seen more frequently

in species with fission-fusion dynamics where one party can have a large numerical advantage over their rival. These lethal aggressions can benefit the victors by increasing their territory, hence, food resources and reduce the number of future competitors or rivals who can form coalitions against them (Watts et al. 2006; Wrangham and Peterson 1996). The exact motivation behind lethal aggressions is still debated as death can merely be the unintentional result of fierce aggression and large injuries sustained to one of the competitors. Lethal coalitionary aggression has also been observed in ancestral human societies. For example, the Yanomamö tribal society of Amazonia where individuals who show stronger alliances are more likely to fight together and this can often be in the form of lethal aggression (Macfarlan et al. 2014). Although it is worth noting these coalitions often differ from those of chimpanzees and other non-human primates as the coalitionary partners can be from neighboring communities against a common enemy (Macfarlan et al. 2014). Hunter-gatherer societies also used levelling coalitions mainly involving males, and these were of larger size than seen in nonhuman primate species (Bowles 2006; Pandit and van Schaik 2003). It is thought that these coalitions carry lower costs due to the use of language allowing greater coordination and the greater number of participants reduces the costs for the aggressors (Pandit and van Schaik 2003). Historically, in human societies males are generally more closely related than females and as a result coalitions are thought to have evolved between related individuals within groups against a common out-group enemy similar to that of nonhuman primates.

Conclusion

Coalitions can occur both within and between groups in nonhuman primates. The level of contest within a group can determine the probability and feasibility of the occurrence of within-group coalitions. At too high or too low contest coalitions, within-groups are not expected. At mid-high contest levelling, coalitions are feasible as males fight over access to females and either male

could gain access to the female once a coalition has broken-up a consorting pair. At lower contest, rank-changing coalitions are more likely and may require several aggressive bouts to allow one or both partners to rise in rank. Thus these coalitions should require a reliable partner. In species where male affiliation is common, those males with stronger social bonds may be more likely to form coalitions. Individuals in the same group may also form a coalition against members of another social group. For these, the individuals involved share a common goal of defeating a common enemy, making such coalitions more feasible. In some species, these contests can be intense and lead to physical injury or even death. Such lethal coalitionary aggression has been described as similar to that of human warfare.

Fellatio

Edward Dutton
Ulster Institute for Social Research,
London, UK

Synonyms

[Blow job](#); [Oral sex](#)

Definition

The oral stimulation of the penis, especially to orgasm.

Introduction

“Fellatio” is defined as the oral stimulation of the penis, especially to orgasm. The word derives from the Latin “*fellatus*,” meaning “to suck.” Fellatio is a common form of foreplay in sexual relationships as well as a sexual end in itself. The practice has been documented in animals, in ancient societies, and in contemporary primitive societies, strongly implying that it has some form of evolutionary benefit.

Flying foxes and fruit bats have been documented to engage in fellatio, with sex lasting longer between fruit bats if the male is first fellated

(Tan et al. 2009). The Indian *Kama Sutra*, written in the first century AD, explores the subject of fellatio in considerable detail. The author believed that it was commonly practiced by promiscuous women, that it was a ritually unclean practice, and that those who were known to engage it in were often shunned by civilized society. Homosexual fellatio is depicted on the Greek Attic red figure kylix, which has been dated to around 510 BC. Anthropologists have recorded fellatio among assorted tribal groups. The initiation rite of passage of the Sambia, of Papua New Guinea, involves prepubescent boys, aged between 7 and 10, daily fellating older males and swallowing their semen (Soble 1997, p. 124).

Fellatio and Evolution

There is much debate on how the practice of fellatio may have evolved. A number of studies have indicated direct benefits in terms of fertility and health. The first benefit is that oral sex, as foreplay, makes fertilization more likely. Tan et al. (2009) suggest that fellatio-related foreplay increases the degree to which the penis is lubricated, increases the size of the erection, and increases the length of intercourse, heightening the level of secretion from the pituitary gland. All of these factors, they argue, increase the likelihood of successful fertilization. Secondly, the same researchers suggest that saliva may reduce the risk of passing on certain sexually transmitted diseases, ensuring a healthier partner and offspring.

Thirdly, research has shown that when a woman regularly swallows her partner's semen, her immune system becomes used to it to, making it more likely that the mother's immune system will accept the proteins in the father's semen. It has been found that many miscarriages, or preterm births, occur because the mother's immune system treats these proteins, in the fetus, as foreign bodies. It has been found that 82% of women without preeclampsia (a condition marked by high blood pressure during pregnancy which can lead to miscarriages and preterm births) regularly practiced fellatio on their partner, but only 44% of

those with preeclampsia did (Koelman et al. 2000). Accordingly, fellatio aids the birth of offspring who are more likely to survive.

Thus, fellatio appears to have evolved, in part, because it is associated with fertility and health. However, parallel dimensions of its evolution have been suggested. Pham and Shackelford (2013) proposed that infidelity detection may be one reason why women may wish to fellate their partners. In a context of relatively poor cleanliness, it is possible that cues of infidelity could be unconsciously picked up through tasting the penis. Pham et al. (2015) found that both men and women reported being more satisfied with their relationships the more oral sex they had and length of relationship was moderately inversely correlated with frequency of and length of oral sex. Thus, part of the purpose of oral sex would appear to be simply bonding. Indeed, giving oral sex within a relationship has been shown to be positively associated with Agreeableness (Pham et al. 2015), which is itself associated with the capacity to foster strong bonds.

Fellatio and Religion

This bonding dimension would be consistent with the practice of fellatio by children in Papua New Guinea on older males. The practice is likely to create a bond between the two males, inducing the older male to assist the younger one in times of need. In this sense, it can be seen to elevate in-group cooperation, and it has been found that internally cooperative groups, all else being equal, tend to triumph over less internally cooperative groups (see Sela et al. 2015). In addition, among the Manchu people of China, a mother may show affection to her son, under the age of 2 years, by kissing his penis or putting his penis in her mouth (e.g., Renteln 2004, p. 243, footnote 49).

Moreover, it has been argued that, to a great extent, religion should be understood as an evolutionary strategy which renders individuals and groups more likely to survive under conditions of natural selection (e.g., Sela et al. 2015).

Consistent with this, many forms of behavior which religious groups promote as divinely mandated have been shown to ultimately promote selection (Sela et al. 2015). Homosexual fellatio in New Guinea tribes – among heterosexual males – reflects a central part of the tribes' belief system. They believe that young boys do not yet have semen and so they must acquire it from other men via fellatio and acquire as much of it as possible.

Fellatio, Group Differences, and Life History Strategy

A number of studies have found group differences in the extent to which fellatio is performed. If a significant dimension to fellatio is bonding, then this is to be expected. Rushton (2000) has argued that different racial groups vary in their life history speed, in a model known as Differential *K*. Fast life history (LH) strategists, evolved to a plentiful but unstable ecology, tend to invest more resources simply in reproduction. As life is unpredictable, they are evolved to seek out and copulate with as many fertile and healthy people as they can, investing little energy in their partners and hoping some offspring survive. Slow LH strategists, in a harsh yet predictable ecology, reach the carrying capacity for their group and start competing to a greater extent with each other. This selects for quality over quantity. Accordingly, they invest more energy in the nurture of their (smaller number of) offspring and more energy in their (smaller number of) sexual partners, to ensure their offspring's survival. They create strongly bonded units. Accordingly, to the extent that fellatio is a matter of bonding, there should be group differences in its extent.

Rushton argues that sub-Saharan Africans are, on numerous measures, faster life history strategists than are Caucasians. Pham et al. (2015) have shown that Agreeableness (an aspect of a slow LH) positively predicts performing oral sex. The available studies on group differences in fellatio

are consistent with this. They all find that African Americans, compared to Whites, are markedly more likely to have never been fellated or to have never fellated and they are more likely to have experienced or performed fellatio in a relationship only after the performance of penetrative sex, with this ordering being reversed in Whites (e.g., D'Souza et al. 2014). Unfortunately, studies comparing White and East Asian people are confounded by the fact that relatively young samples are employed (e.g., Meston et al. 1996) and East Asians appear to become sexually active later than White people (Rushton 2000).

Consistent with the idea that fellatio is associated with a slow LH, some research has found evidence that lower SES people are less likely to engage in fellatio than higher SES people (e.g., Schofield 1965). Black people in the USA, on average, have lower socioeconomic status than White people, so this may be the mediating factor. Lower SES people, on average, follow a faster LH strategy than higher SES people (Rushton 2000).

Future Research

In terms of future research, it would be of great interest to establish in more depth the extent to which the practice of fellatio varies between different groups and thus the degree to which it may be a reflection of life history strategy. Related to this, it would be interesting to understand the origins of different attitudes to fellatio in different religions, as it may be that fellatio is more or less adaptive in different ecologies. Exploration of the Manchurian practice of briefly fellating babies and toddlers would also be interesting. In Western countries, young children are sometimes patted on the buttocks by adults, supposedly as a form of affection, or at least they have been historically. It is possible that there may be some evolutionary reason behind what some would regard as the unacceptable sexual touching of young children, though precisely what is a matter for future research to address.

Definition

Men use various forms of physical (homicide and intimate partner abuse) and sexual (rape and sexual coercion) aggression against women to control female sexuality and circumvent female sexual choice. Female age predicts physical and sexual forms of men's violence. Young, fertile women, as compared to older women, are reproductive commodities and, thus, are the primary targets of men's aggression.

Introduction

Men have evolved a sexual preference for youthful, reproductive-age women. Men's sexual preference for younger women is one feature of human male sexual strategy (Kenrick and Keefe 1992; Thornhill and Palmer 2000). Youthfulness is a reliable indicator of fertility. Ancestral men who were primarily attracted to fertile women thereby increased their reproductive success. Additionally, young women are more valuable to men as mates. Men report that youth is one of the most important characteristics in a partner, across 37 cultures (Buss 1989). Buss (1989) found that men in all 37 cultures rate youthfulness as a

highly desirable trait in a marriage partner. On average, and across cultures, men prefer a mate that is roughly 24 years old, an age near women's peak reproductive value, or expected future reproduction. Youthfulness is an important trait among men's preference not only for long-term mates but also for short-term mates. Across five cultures, younger female escorts advertise a higher fee for their services, compared to older escorts (Dunn 2018). Given an evolved desire for youth, men are willing to pay younger escorts more money than older escorts. Younger escorts present more observable signs of fertility and reproductive value than do older escorts and therefore can charge and are paid more.

Men use sexual and physical aggression against women to deter rivals, secure sexual access, circumvent female sexual choice, and minimize investment for sexual access. Men may use physical aggression, such as partner violence, to dissuade a woman from desertion or infidelity. Sometimes, however, men kill their partners to thwart abandonment or cuckoldry. Men use sexual aggression, such as rape, to secure sexual access without providing investment or resources. Men's use of aggression is an aspect of a sexual strategy designed to control women's sexual behavior to thereby secure exclusive sexual access to her. Given men's preference for youth and fertility, men primarily use aggression against younger women.

Men with younger, reproductive-age partners are more likely to inflict violence on them to control their sexual behavior (Smuts 1992). Young women are more fertile and are more likely to reproduce than are older women. Whereas women can be certain that an offspring is their genetic kin, men can be deceived into providing resources and investment to an offspring that is not their genetic kin. Younger women pose greater risk than do older women to men's reproductive success: the costs of a reproductive-age women's sexual infidelity or desertion are more devastating to men, as compared to an older partner's deceptions. Older women can no longer reproduce and cannot cuckold or trick a man into investing resources into a child that is not his genetic kin. Thus, the prospects of sexual infidelity and

paternity uncertainty/cuckoldry motivate men's aggression against *younger* women more frequently than against older women. To avoid being deceived into raising genetically unrelated offspring, men deter women with violence. Ancestral men who successfully used aggression against younger women, thereby convincing a woman to stay in a relationship or to deny a potential mate poacher, were likely to achieve greater reproductive success. In sum, younger women are greater assets to men than older women, given younger women's greater fertility and reproductive value; thus, sexual infidelity, abandonment, and lost sexual opportunities are distressing events for men, resulting in men's use of aggression – especially directed against younger women.

Intimate Partner Violence and Homicide

The age of a woman predicts the likelihood she will be the target of intimate partner violence or homicide. Young women aged 16–24 years report the highest levels of nonlethal intimate partner violence (Rennison and Welchans 2000). Intimate partner violence may take multiple forms, including physical violence and emotional or psychological aggression (e.g., threats of physical violence or defection). Buss and Duntley (2011) suggest that intimate partner violence may reflect a mate retention strategy in which men attempt to deny a partner's relationship defection or infidelity. Intimate partner violence functions to control a woman's sexuality and to thwart rival sexual access. Male sexual jealousy is the most common cause of intimate partner violence and homicide (Daly and Wilson 1988). To combat the threat of cuckoldry, male sexual jealousy may have evolved as a mechanism of infidelity prevention or detection and as a motivator of subsequent, sometimes violent, behavior (Buss 2000). Given men's evolved interest in securing young, fertile women with high reproductive value as mates, male sexual jealousy should be especially sensitive in the context of mateship to younger women. Because younger women are more desirable to male rivals, male sexual jealousy may motivate

men to use aggression against their partner to stop them from defecting. In sum, men may benefit by restricting a younger mate's, as compared to an older, nonfertile mate's, sexuality through physical aggression because this aggression ancestrally increased male reproductive success by lowering the risk of cuckoldry and abandonment.

Intimate partner violence occasionally escalates to homicide, particularly targeting young women. Young women are more likely to be killed by their partner than are older women (Shackelford et al. 2000). Specifically, women aged 15–24 years, within the peak reproductive years, are most likely to be killed by their partner (Daly and Wilson 1988). The greatest risk of uxoricide (wife-killing by husband) in Canada fell on the youngest registered wives (Wilson et al. 1993). These women were also in the 15–24-year age range, aligning with an evolutionary perspective on men's use of strategic aggression against younger women. Another study found that the risk of uxoricide decreases with a woman's age (Shackelford 2001). Men's partner-killing may be produced by an evolved psychology designed to produce death in these circumstances (Buss 2006). Specifically, ancestral men may have increased their relative reproductive success by permanently dissuading their partner from defecting or committing sexual infidelity – and thereby eliminating entirely any risk of cuckoldry or defection. Researchers have investigated whether younger women are killed more often than older women because younger women are mated to younger men, who commit the majority of violent crimes. The results of this research found that younger women are more likely to be killed across *all* male partner age groups (Shackelford et al. 2000). Because young, fertile women have the highest reproductive value, it follows that men should primarily commit physical aggression against younger mates, which research supports.

Stalking

Buss (2006) proposed that stalking is a feature of men's reproductive strategy. Stalking is an extreme form of mate guarding and refers to a range of persistent psychological and physically

abusive activities, often in the form of spying, surveillance, or threats (Buss 2000). Stalking may function as a mate retention strategy to deter rivals/mate poachers, to acquire new mates or ex-mates, or as a sexual predation or exploitation tactic (Duntley and Buss 2012). Duntley and Buss (2012) suggest that psychological adaptations may facilitate and motivate stalking. The psychology of stalking may have evolved because it increases the likelihood of mate reconciliation and dissuades rivals, which thereby increased the ancestral stalker's reproductive success.

Similar to intimate partner violence and homicide, women within the peak reproductive-age bracket are most likely to be the victims of stalking. A majority (56%) of college-aged (18–24 years) women report having been stalked (Buss 2000). Additionally, Buss (2000) reported that 80% of women who have been stalked in their lifetime indicated that they were younger than 40 years at the time of the stalking. Most of those women were between 18 and 29 years, with an average age of 28 years. Given that fertility peaks in the mid-20s (Thornhill and Palmer 2000), most stalking victims were within the peak reproductive period, suggesting that stalking may be produced by an evolved psychology. Most women report that the men who stalked them did so to keep them from leaving the relationship (Buss 2000). Women's perceptions of stalking align with an evolutionary explanation of stalking. Stalking also sometimes functions as a tactic to sexually coerce women. When successful, it may deter rivals from gaining sexual access, thereby interfering with female sexual choice. Some (but not all) women who are stalked eventually date the man who stalked them (Duntley and Buss 2012). Because young women are the primary targets of stalking, the men who successfully stalk them and gain sexual opportunities, while fending off rivals, may have been ancestrally more reproductively successful.

Rape

If rape is produced by an adaptation that increased ancestral male reproductive success, one might

expect that rapists would target fertile, reproductive-age women, as opposed to older, nonfertile women. Similar to men's physical aggression and stalking behaviors against women, rapists target youthful, reproductive-age women (Thornhill and Thornhill 1983). It is possible that a victim-preference mechanism, such as a desire to copulate with younger, more attractive women, may have increased the ancestral reproductive benefits of rape. Ancestral men who successfully raped reproductive-age women may have thereby increased their reproductive success, without providing resources or investment to the woman and subsequent offspring, thereby circumventing female sexual choice. In an analysis of over 34,000 robberies, the highest risk of being sexually assaulted or raped during a robbery fell on women aged 15–29 years (Felson and Cundiff 2012). Male perpetrators of *all* age groups that committed sexually aggressive acts during robbery targeted women in this reproductive-age bracket. However, there was no difference between instances of rape and of sexual assault during robbery. The adaptation hypothesis suggests that rape is a reproductive strategy with which ancestral rapists increased their reproductive success by circumventing female sexual choice (Thornhill and Palmer 2000); sexual assault alone would not have increased ancestral reproductive success. Thus, the adaptation hypothesis of rape is not fully supported; however, those who exclusively committed sexual assault primarily targeted younger women, so sexual aggression as an adaptation cannot be dismissed. Additionally, women may have evolved mechanisms to prevent being raped (Buss 2006). Given the costs of rape (e.g., caring for a child without paternal investment), young women are especially fearful of situations that put them in sexual or physical danger (Scott 2003). Scott (2003) reported that as a woman's age increases, her fear of being a victim of various forms of victimization, including sexual aggression, decreases. Research indicating that younger women rate dangerous sexual situations as more distressing than older women provides evidence for evolved anti-rape mechanisms in women. Anti-rape mechanisms may have coevolved in response to evolved sexual aggression

mechanisms in men. However, the tendency for men to rape younger women, as compared to older women, does not convey whether men have specialized rape adaptations or if rape occurs as a by-product of other evolved mechanisms (e.g., attraction to youthfulness).

In uniquely violent cases, young women (20–24 years) are the special targets of rape-homicide (Shackelford 2002a). Although it has been hypothesized that younger women may be special targets of men's aggression because they are more frequently associated socially with younger men, who commit most violent crimes, including homicide, rape, and rape-homicide (Daly and Wilson 1988; Thornhill and Palmer 2000), Shackelford (2002a) provides evidence to the contrary. Young women were *not* overrepresented in cases of theft-murder, only in rape-homicide cases, suggesting that association with younger, violent males is not the cause of younger women's greater risk of rape-homicide. Instead, women's age is the primary predictor of men's perpetuation of rape-homicide. Shackelford (2002b) also found that younger women are more likely to be the victims of rape-homicide involving two or more male offenders, further indicating that rape-homicide is not an outcome of young women being more frequently socially associated with younger men. However, most men who rape do not subsequently kill the victim, perhaps because rape may have increased ancestral reproductive success only when the victim lives to produce a child (Buss 2006). Shackelford (2002a, b) suggests that men who commit rape-homicide kill because the costs of detection may outweigh the benefits of reproduction or because the perpetrators have especially low impulse control or other psychopathic characteristics.

Conclusion

Younger women, as compared to older women, tend to be the target of men's aggression. Younger women are the primary victims of men's aggression because fertile, reproductive-age women ancestrally afforded men the greatest reproductive success and social status. If controlling a younger women's sexuality, as compared to an older,

nonfertile woman's sexuality, conferred reproductive benefits on ancestral men, mechanisms may have been selected that motivate male sexual proprietariness. Intimate partner violence and homicide are male tactics used to inhibit young women from committing sexual infidelity or deserting the relationship. Stalking may be used by men as a fear-inducing mate retention strategy, particularly targeting younger, reproductive-age women. Men may rape younger women to increase their own reproductive success without investment, thereby denying the woman sexual choice and freedom. In sum, men of all ages may increase their own reproductive success by using physical and sexual aggression primarily against young, fertile women.

Female Choice and Sexual Conflict Theory

Catherine Salmon
University of Redlands, Redlands, CA, USA

Synonyms

[Epigamic selection](#); [Female mate choice](#)

Definition

When females are the choosy sex and retain primary control over which males they will mate with. Thus, members of the lower investment sex, usually males, compete for features that are attractive to members of the high investing sex, usually females. In this sense, females choose on the basis of male displays or traits.

Introduction

The outcome of sexual selection is the evolution of secondary sexual characteristics that are designed to attract and compete over mates. Traits that evolve via sexual selection do so as a result of competition for mates (intrasexual competition) or mate attraction (epigamic selection). Intrasexual competition is competition between members of the low investment sex (usually males) for copulations with the high investment sex (usually females). Since males are usually the low investment sex, they are the most intrasexually selected. This results in traits beneficial for competing with other males such as organs of threat (antlers, large size, aggressiveness, etc.). In some cases, these traits will be used in direct physical combat with other male; in other cases, they may be used to establish dominance hierarchies where the males at the top monopolize mating opportunities. An example of intrasexual selection for size is found in elephant seals where males are substantially larger than females, spend much of their time competing for females, and the most dominant males father the majority of pups in any given season.

Epigamic selection is competition between members of the low investment sex for features that are attractive to the high investment sex. As with intrasexual selection, the sex that invests less per offspring is usually the male. Thus, this type of selection is often referred to as female choice; the females choose on the basis of male displays or attributes. The result of female choice is the elaboration of displays, coloration, and courtship rituals as the males try to “impress” the females by competing with other males via

display mechanisms. Under female choice, highly elaborated traits can evolve, such as the peacock’s tail (Petrie 1994). Such traits exist because of the female preference for them. Males with those traits, or the most impressive examples of such, were the most successful at reproducing and passed those traits on to their offspring. However, this raises the question of what benefit those traits are to the reproductive success of females? Why do they choose them?

Runaway Selection or the Sexy Sons Hypothesis

The effects of female choice can lead to what Fisher (1915, 1930) referred to as runaway selection. In this process, females are initially predisposed to favor a particular male trait (reason unspecified) and those males possessing the favored trait attract females and experience greater reproductive success, which in turn passes on the male trait as well as the female preference for that trait. The joint selection for that trait creates a positive feedback loop that continuously favors both these traits (the trait in males and preference for it in females). The result can be “runaway” selection of the male trait, leading to the evolution of more elaborate or extreme versions of the original trait. This has been used to explain the evolution of elaborate male ornamentation or other secondary sexual traits that would seem to reduce the survival of those who possess them, though presumably the runaway process would cease when the survival costs outweigh the benefits of attracting mates (Pomiankowski and Iwasa 1993). Where does the original preference for the trait on the part of females come from? The trait might have had some adaptive value, as a health indicator, for example, bright coloration revealing the male to be free of parasitic infection. Or the trait could have been preferred by females for purely arbitrary reasons unrelated to fitness. For example, a bird could have a color preference or sensory bias due to a food item of that color being a major component of their diet. As a consequence, anything with that color, including a male of their species, may be

perceived as attractive. It has been suggested that such sensory bias has influenced female choice in guppies. Rodd et al. (2002) suggested that male color patterns are the result of female choice of males with orange spots due to the attraction of both sexes to inanimate orange objects. Guppies frequently eat orange food items; thus, the suggestion is that selection for easy detection of orange food items results in selection for preferences for orange males. However, Houde (1997) and Kennedy et al. (1987) suggest that female choice for males with orange spots is adaptive because males must ingest carotenoids to produce these colors and thus the bright color could be an honest indicator of male quality.

Related to runaway selection is the sexy sons hypothesis which states that females choose males with attractive traits, such as large size or bright colors, because these traits will be passed onto their sons who will also be able to attract many mates. From this perspective, females that choose a male whose genes will give her sexy sons will have a good chance of having their own genes passed on by her sexy sons. Evidence in support of the sexy sons hypothesis of female choice has been found in several bird species including European starlings (Gwinner and Schwabl 2005) and beetles (Pai and Yan 2002) though others suggest that good genes are what females are choosing for as will be discussed next.

The Handicap Principle and Honest Advertisements

Why do males evolve extravagant costly traits like peacock tails or nest displays like satin bowerbirds? While these traits help them attract mates, they also attract predators, can make it difficult to escape from them, and are metabolically costly.

Zahavi and Zahavi (1997) suggested that a trait would be selected for if it provides a cost to its carrier that indicates something about the quality of the carrier. The peacock is often highlighted as an example of Zahavi's handicap principle with the male tail serving as a costly signal. Peahens select from a pool of possible mates. Assuming that genes are all that the males

provide and that males vary in genetic quality, peahens should aim for the male with the best quality genes available.

As genetic quality cannot be directly assessed, peahens attend to cues that males provide. Peacocks advertise genetic quality via large, colorful, symmetric tails. Such an ornament is a handicap in that it is energetically costly to build and difficult to hide from predators. A poor quality male would not be able to produce an impressive tail as his energies are required just for basic somatic maintenance as well as predator avoidance. A high quality healthy male, however, can afford the cost of such an advertisement. Since only high quality males can afford impressive tails, peahens prefer males with large, bright, symmetrical tails to mate with as they serve as honest indicators of male quality (Loyau et al. 2005; Petrie 1994). Studies have documented similar impacts of female choice on advertisements in long-tailed widowbirds (Andersson 1994), the vocalizations of male American Bison (Wyman et al. 2008). Studies in humans have also suggested a role for honest advertisements in the mating arena including face shape preferences, such as male face shape as an indicator of immunocompetence (Scott et al. 2014), and humor on the part of males as an indicator of intelligence and good genes (Miller 2000; Greengross and Miller 2011).

Is Female Resistance a Form of Female Choice?

Female resistance is defined as the process by which females evolved to resist male control of mate choice, allowing females control over their own mate choice decisions. Thus, female resistance can be seen as a form of sexual conflict through which females use resistance to select mates and perhaps shape the evolution of male structures and behaviors. Female resistance to males might be designed to gain indirect fitness benefits by allowing the female to select for males based on their ability to manipulate females or their physical strength in cases where male defense of offspring and mate might be required, and to select for "better genes" or material

resources (Cordero and Eberhard 2003; West-Eberhard 2014).

Female selection of antagonistic traits in males via resistance has been documented in gladiator frogs (Kluge 1981). However, the evidence with regard to the role of female resistance in female choice in other species is rather limited. In the case of human females, it has been suggested that the commitment skepticism bias in Haselton and Buss (2000) is a form of filter resistance that deters females from being deceived about the costs of mating that a male may impose due to a lack of commitment. Such a bias on the part of females requires males to clearly demonstrate their willingness to commit and ability to provide benefits rather than impose costs.

Conclusion

While mate choice was once viewed as something males engaged in, males mainly competing for access to females, it is clear that females also engage in mate selection and their choices influence the evolution of male traits. Females may exert choice through inciting male display of honest advertisements of quality in addition to antagonistic displays, including female resistance. Females may also shape male traits via selection for the production of sexy sons.

Female Choice for Men High in SDO

Ray Garza

The Oklahoma Center for Evolutionary Analysis (OCEAN), Oklahoma State University, Stillwater, OK, USA

Synonyms

[Dominance](#)

Definition

Female choice for men with high SDO describes preferences for men who are competitive, formidable, anti-egalitarian, and prefer short-term mating.

Introduction

In mate choice, females often face a trade-off in choosing the best possible mate where genetic quality and parental investment are prioritized. Males who exhibit good genes may also be men who are socially dominant and competitive, and therefore, more likely to be interested in short-term sexual encounters. Females seeking dominant males may be attempting to secure the benefits bestowed by them, such as access to material resources, protection from threats, and producing strong and healthy children (Kruger and Fitzgerald 2011). However, preferences for dominant males may be modulated by factors associated with fertility, relationship context, and masculinity. Recent research has found evidence on the link between social dominance orientation and political conservatism, thus, it is worth mentioning if female mate choice for socially dominant males also carries over to preferences in political attitudes associated with social dominance.

Female Choice for Men High in Social Dominance

Why do females choose males who are high in social dominance orientation as mates? Socially dominant males, as measured by the SDO, are males who are callous and manipulative, desire power, oppose income redistribution, are formidable, and tend to pursue short-term mating strategies (Sinn and Hayes 2018). Although these characteristics are also associated with low paternal investment, females who pursue dominant males are benefitting from the advantageous of males who are competitive, can obtain access to material resources, and have increased genetic quality. Access to these types of mates may be dependent on the type of relationship context that females are pursuing, such as prioritizing a short-term partner over a long-term partner. In searching for dominant males, females pursuing short-term mating may benefit from healthy offspring, immediate resources acquisition, and protection from threats. However, females searching for long-term relationships with dominant males run the risk of an intersexually competitive male who may not be willing to invest heavily in one female. Dominant males have been found to be associated with preferring short-term mating, aggressive behaviors, and having highly masculine appearances and behaviors. This contrasts with males who are considered high in prestige, who are associated with preferring long-term relationships but achieve social status through noncoercive means (Kruger and Fitzgerald 2011).

Preferences for dominant males can be modulated by fertility status. If females are to gain from choosing dominant males, then it should occur during a time period that corresponds with peak fertility, where reproductive advantageous (i.e., genetic quality) are most likely to occur. Research investigating fertility status and preferences for dominant traits in men have found that the point of the menstrual cycle that corresponds to peak fertility, as measured by hormonal fluctuations, influences dominant trait preferences. Women have been shown to prefer dominant traits

when luteinizing and follicular stimulating hormones are highest, which are hormones that are associated with the fertile window. Interestingly, as aforementioned, these preferences were for short-term partners, which suggests that women may upregulate interest in cues to genetic quality during the fertile window and downregulate interest in these cues during infertile times of the menstrual cycle (Lukaszewski and Roney 2009). It is important to mention that recent studies investigating the role of hormones in preferences for dominant men have failed to find an effect for fertility status (Garza and Byrd-Craven 2019; Jones et al. 2019), suggesting that hormonal detection in dominant men is more complex than previously thought.

Although it is known that women pursuing short-term mating relationships have preferred men high in social dominance, are salient physical traits able to account for those preferences? Men who display dominant and masculine physical characteristics are considered sexually attractive (Swami and Tovee 2005), and it can be argued that these physical characteristics can account for the advantageous gained from traits associated with social dominance, such as resource acquisition, and offspring and mate protection. Men with V-shaped bodies are considered physically dominant and masculine (Buunk and Dijkstra 2005), and these traits can explain the reason why females are attracted to men who are socially dominant because they have the physical capability to carry out socially dominant behaviors. Women have been known to be attentive to physical characteristics associated with dominance, such as preferring taller men, symmetrical men, and body types that resemble the android pattern, where fat distribution is deposited on the upper region of men's bodies. Research investigating determinants of romantic partner desirability has shown that dominance and a lower waist to shoulder ratio is a reliable predictor in desirability for a one-time sexual encounter; however, dominance did not mediate the relationship between WSR and desirability for a sexual encounter (Braun and Bryan 2006). Simply put, the physical

characteristics associated with dominance (i.e., low WSR) were considered desirable by women.

Do preferences for social dominance relate to preferences for sociopolitical attitudes, such as egalitarianism? Social dominant characteristics, like formidability, provide men with the tendency to be more competitive and benefit from successes in inequalities in status and resource distribution (Price et al. 2017). Just as some physical characteristics are associated with dominance, research linking social dominance with sociopolitical attitudes has shown that body formidability, as measured by a composite of upper body strength, is negatively related to sociopolitical egalitarianism and support for redistribution. In addition, body formidability has been shown to be positively related to social dominance orientation, which may suggest that men with certain types of physical characteristics indirectly display psychological attributes associated with dominant behaviors. Studies with larger samples have also demonstrated that formidable characteristics are positively related to anti-egalitarianism (Petersen and Laustsen 2018). Similarly, men with higher bicep circumferences (i.e., formidability) have been shown to be more supportive of military action, and this effect has been larger in men than women (Sell et al. 2017).

Given the relationship between formidability and sociopolitical attitudes, and women's preferences to dominant men, what if any is the relationship between female mate choice to men with political ideologies associated with dominance, such as conservatism? Most research has focused on women's mate preferences to men that display dominant characteristics, and most research on social dominance has focused primarily on same-sex attributions of formidability and egalitarianism. Literature on political behavior has identified patterns in political ideology identification, where attractive individuals are likely to claim Republican or conservative parties (Peterson and Palmer 2017). However, it is unclear whether female mate choice for socially dominant men also reflect preferences for political ideologies that overlap with social dominance. In addition, research should begin

investigating females' own level of dominance and political ideology and their preferences for males with similar characteristics. With this approach, testable predictions can be formulated regarding women's mate preferences to socially dominant men, such as women's level of social dominance and/or egalitarianism and its association with men's physical characteristics that reflect social dominant traits (i.e., formidability, strength).

Conclusion

In conclusion, preferences for socially dominance men (SDO) can provide many direct benefits to women, such as resource acquisition, status transmission, and protection against threats to offspring. However, preferences for dominance is mitigated by many factors that can enhance those direct benefits, such as relationship preferences and fertility status. An important thing to note is that women's preferences for physical characteristics associated with dominance has shown strong empirical support, yet female preferences for SDO and physical characteristics has not been explored. Lastly, given the relationship between SDO and sociopolitical egalitarianism, future research could begin investigating if female preferences for SDO men also overlap with their own political ideologies in addition to the political ideologies of potential mates.

Female Copulatory Orgasm

John P. Towne and Gordon G. Gallup

[Orgasm triggered by sexual intercourse](#)

Definition

Emerging evidence suggests that orgasm elicited by sexual intercourse evolved to give women feedback about mate choice and to induce changes that increase the likelihood of impregnation.

Introduction

Orgasm in men is nearly universal. However female orgasm is much more variable in frequency. Many theories have been advanced to explain the advantage that orgasm might confer in women. This entry examines recent evolutionary-based interpretations of female orgasm.

One of the leading interpretations of female orgasm is that because orgasm produces vaginal and intrauterine contraction it enhances sperm transport and retention, and it enables a woman who mates with multiple partners to selectively experience orgasm with the man with the best genes, thereby increasing the likelihood of conception and the corollary fitness of her offspring. This interpretation is supported by a study with undergraduate college students where female orgasm frequency and intensity were positively correlated with partner attractiveness (Gallup et al. [2014](#)). Frequency of female orgasm was also correlated with partner family income level, suggesting a mechanism for identifying mate-provisioning ability. Additional support for this

interpretation comes from a study where it was discovered that a woman's likelihood of orgasm was positively correlated with how attractive the woman thought her partner was to other women (Sela et al. [2015](#)).

Sperm Retention

There are other reasons to believe that orgasm increases the chance of impregnation. One study found that the experience of female orgasm increased the level of sperm retention after copulation for up to 8 days (Baker and Bellis [1993](#)). Although this effect gradually declined with time, any orgasm which occurs afterward (including noncopulatory) served to reinstate and promote sperm retention. Additionally the amount of sperm retained from the first copulation was negatively correlated with the amount retained during a second copulation. It has been shown that oxytocin triggered by orgasm produces a dramatic increase in uterine peristaltic movements, which selectively propel sperm into the fallopian tubes (Wildt et al. [1998](#)). Coupled with research which links levels of oxytocin with intensity of orgasm (Berlow [2004](#)), it is reasonable to suppose that as orgasm intensity increases so should sperm transport and the likelihood of impregnation.

Multiple Orgasms

One of the biggest differences between male and female orgasm is the latter's ability to experience multiple orgasms in a single encounter. The likelihood of experiencing multiple orgasms is positively correlated with female orgasm frequency and intensity, and the age of her partner (Gallup et al. [2014](#)). Since the frequency and intensity of female orgasm is correlated with partner attractiveness and family income, this suggests that the experience of multiple orgasms functions as a signal that the woman has found a mate of significant fitness and provisioning potential. In addition, multiple orgasms may result in an even greater production of oxytocin thereby furthering the chances of conception.

Sedative Properties of Orgasm

Other adaptive features of female orgasm are its sedative properties. Females that experience sedative effects of orgasm are more likely to remain in a prone position for an extended period of time following insemination, and would benefit from reduced “flow-back” leading to increased sperm retention. The release of both oxytocin and dopamine in the brain during orgasm fall sharply afterward. This sudden surge and withdrawal of neurochemicals creates a feeling of being drained of energy; meanwhile as dopamine and oxytocin levels fall, prolactin levels rise which lead to feelings of satiation (Berlow 2004). Additionally prolactin increase following orgasm in females is four times greater after intercourse than masturbation (Brody and Kruger 2006). The sedative effect of orgasm is further implicated by a survey where 32 % of women reported the use of masturbation as an aide to help them fall asleep (Ellison 2000). The sedative effects of orgasm may play a role in mate choice by ensuring retention of the male’s sperm, prevention of further insemination by potentially lesser-quality males, and promotion of pair-bonding between the female and the high-quality male.

Extra-Pair Copulations

The role of orgasm during extra-pair copulations (EPC) may also serve to increase the likelihood of conception by the extra-pair (EP) male. Previous work has found that women are more likely to experience an orgasm and report orgasms of greater intensity during an EPC (Gallup et al. 2006); some research has even found that women are more likely to have multiple orgasms during EPCs. Baker and Bellis (1993) report that women who engaged in EPCs were more likely to retain the sperm of their EP mates and less likely to retain sperm from their committed partner (CP). This was due to the fact that orgasms were much more likely during an EPC, and that the number of noncoital orgasms increased after the EPC. The greater likelihood of orgasm during an EPC served to retain more sperm and the increase in

noncoital orgasm frequency (largely as a consequence of masturbation) between the encounters serves to further promote retention of the EP sperm and block the CP sperm.

Lastly for a woman with a large number of children sired by her CP, each additional child becomes an increasingly redundant sample of the father’s genes. The reason for this is that the proportion of her partner’s genes not previously sampled is reduced by 50 % with each successive child. As a result, by the time a woman has three children sired by the same man she will have sampled on average 87.5 % of his genes. As a consequence conception as a result of an EPC/change in paternity would function to dramatically increase the range of genetic variance among her existing children, and genetic variation may be a hedge against an uncertain future.

Conclusion

Emerging evidence suggests that female orgasm functions to promote the movement of sperm up through the female reproductive tract and increase the likelihood of impregnation as a consequence. Research also suggests that female orgasms promote greater retention of sperm, and coupled with the sedative properties of orgasm women are more likely to remain in a prone position for an extended period of time following coitus which diminishes the loss of semen. There is also evidence that orgasms give women feedback about mate choice; i.e., females in committed relationships with an intelligent, healthy, high quality man are more likely to experience orgasm and their orgasms are also experienced as being more intense.

Definition

Rape is defined as “penetration, no matter how slight, of the vagina or anus with any body part or object, or oral penetration by a sex organ of another person, without the consent of the victim” (The United States Department of Justice 2012). Rape counter-adaptations entail specialized mechanisms that reduce women's risk of male sexual coercion.

Introduction

In the USA, an estimated one in six women will be raped in their lifetime, with 29% of victims being between the ages of 18–24 years (Tjaden and Thoennes 2006). However, it is likely these figures only represent a small number of rape victims, as rape is seldom reported to the police. Approximately 15% of victims are estimated to report sexual violence to the police (Office for National Statistics 2013). Low reporting may stem from societal misconceptions surrounding rape, including victim blaming. What is more, rape often has serious psychological consequences for victims. For instance, victims often sustain posttraumatic stress disorder (PTSD) following rape.

This chapter reviews the literature on evolutionary explanations of rape. In particular, it will discuss research that has investigated whether women have rape counter-adaptations. The discussion will be necessarily restricted to rape perpetrated on women by men. Although women can perpetrate rape and men can be the victims of rape, most rapes are perpetrated by men against women (Office for National Statistics 2013). Accordingly, evolutionary explanations of rape have been concerned with accounting for male-perpetrated rapes against females.

Costs of Rape

The evolutionary framework assumes that animals strive to attain two fundamental goals: survive and reproduce offspring. In women,

successful reproduction is considered to be passing on the strongest genes and resources that will increase the chances of survival of the species. During peak fertility, women aim to attract the highest quality mate to achieve this. Successful reproduction for males involves the quantity of their offspring, with less importance being placed on their quality (Trivers 1972). In order to survive, some psychologists propose that humans weigh up the costs and benefits of putting themselves in certain situations, which could prove fruitful, in terms of achieving resources to benefit fitness, such as meeting mates, but could also pose risks in terms of encountering aggressive mates, for example. For the purposes of this chapter, benefits refer to outcomes of a positive sexual encounter (e.g., increased chances of successful reproduction), while costs refer to the consequences of a negative sexual encounter (e.g., decreased chances of successful reproduction). Rape, therefore, is a high cost due to the reduced chances of a successful and wanted reproduction.

Perhaps one of the most obvious costs of rape is the psychological pain felt by the victim. With regards to reproductive fitness specifically, however, pregnancy arising from rape is considered to be one of the highest costs of rape. Pregnancy reduces a woman's reproductive fitness significantly because she must carry and raise offspring with a mate not of her choosing, thereby limiting her reproductive resources. For many female animals, mate choice is of high importance. However, rape circumvents female mate choice, and so, according to the evolutionary framework, it is particularly costly with regard to unwanted conception.

Evolutionary models emphasize the differential investment that women and men make in reproduction. Relative to men, women have fewer sex cells and they generally provide more time and energy to raising offspring following conception. Therefore, it is detrimental to a woman's reproductive fitness if pregnancy occurs with an undesirable mate and under conditions in which valuable resources to support the offspring are unavailable. Parental investment theory (Trivers 1972) proposes that investing in offspring increases the offspring's chance of survival while

limiting other reproductive opportunities. One hypothesis that can be derived from this is that women must take care to choose a mate who will invest time and provide valuable resources with respect to offspring. Supporting this hypothesis, women are more fearful of stranger rape despite it being much less common than acquaintance rape (Thornhill and Thornhill 1990b, as cited in Thornhill and Palmer 2000). It has been argued that fear is lower in acquaintance rape because, arguably, relative to a stranger, an acquaintance is more likely to provide resources to an offspring of rape, which reduces the cost for a woman. Furthermore, research has shown that psychological pain varies across victims, with women who are married reporting more psychological pain than victims who are single (Thornhill and Palmer 2000). It has been posited that married women suffer more pain because of the potential for abandonment and a loss of resources from their spouse if they are perceived as adulterous. Furthermore, it has also been found that women of a reproductive age who would face greater costs to their future reproductive fitness report more psychological pain (Thornhill and Thornhill 1990a, as cited in Thornhill and Palmer 2000). Women of reproductive age are more fearful of being assaulted and raped, than older women, who in turn are more fearful of a burglary. Fear seems to contribute to the experience of psychological pain, which might account for some of the variation in psychological pain in response to rape. Thus, although pregnancy is one of the most widely researched costs of rape, it is important to recognize it is not the only cost for victims.

Due to the high cost of rape, it has been theorized that women have evolved counter-adaptions in order to reduce the likelihood of rape occurrence (e.g., Thornhill and Palmer 2000). Adaptations are evolutionary solutions to environmental challenges faced by our ancestors (Ridley 1987, cited in Thornhill and Palmer 2000). Adaptive traits are selected through natural and sexual selection. That is, traits that increase "fitness," through successful reproduction and survival, are reproduced in future generations. Thus, adaptations work to increase the chance of reproduction and/or survival. Psychological pain, in particular,

has been theorized to serve an evolutionary function in regards to the adaptation of behaviors and cognitions in order to overcome problems. Thornhill and Thornhill proposed that in regards to rape, psychological pain has an adaptive benefit, focusing a woman's attention on circumstances that may have led to the rape occurring. This would then allow women to avoid a similar situation in the future, with this mechanism being passed on to future generations to allow offspring to avoid rape without ever directly experiencing the psychological and physical pain of rape.

In view of the high costs of rape, it has been proposed that women evolved adaptations to counter rape. These are referred to as counter-adaptations, because, quite controversially, some evolutionary psychologists have hypothesized that rape by a male onto a female has evolved as an adaptive reproductive tactic to spread their genetic make up to a high degree (see Thornhill and Palmer 2000). Thus, a rape avoidance adaptation in women has evolved to counter to this male adaptation. The theory and some of the evidence behind the hypothesis that rape is an adaptive male behavior will now be reviewed briefly. However, the focus of this chapter will be on reviewing the theory and evidence behind the hypothesis that women have evolved counter-adaptations to rape.

Is Rape Evolutionary?

It has generally been thought that rape by a male of a female evolved as a tactic to allow males to spread their genetic make up to a high degree (see Thornhill and Palmer 2000). However, it is important to consider that rape may be a by-product of other evolved male traits, such as a greater desire for sexual variety, a higher sex drive, or aggressiveness.

Although rape may be a byproduct of other evolutionary traits, it is also hypothesized that rape has evolved to increase the chances of successful genetic reproduction in males who cannot receive legitimate consensual intercourse from desirable female partners (see Thornhill and Palmer 2000). It is argued that males who do not have access to desirable attributes for both females and potential offspring are more likely

to rape than those who do. This concept has been shown in male scorpion flies, whereby males who lack the resources (i.e., nuptial gifts) to be selected as mates have been shown to attempt forced copulation (Thornhill 1980). In humans, criminal statistics suggest that men from low socioeconomic areas are more likely to rape, as discussed by Thornhill and Thornhill (1983). High status men are deemed less likely to rape as they are considered to have access to potential partners who would freely give sexual consent, whereas "low status" men may not have this (e.g., see Thornhill and Thornhill 1983). Alternatively, Thornhill and Thornhill (1983) argue that it may be in certain societies, such as in the United States, wealthier men are less likely to be caught or are in a better position to gain legal help to either have a case over turned or to settle out of court. It may also be the case that men who are considered to be "upstanding citizens" or are of a higher class will not be tried as harshly alongside having access to the best legal assistance. Therefore, it may not be the case that men from low socioeconomic backgrounds are more likely to rape than their higher socioeconomic counterparts, but rather, that they are overrepresented in prison statistics because they have inadequate access to legal assistance. It is, therefore, difficult to fully know whether there is a relationship between socioeconomic level and the propensity to rape, as the representation of low status males in rape data is likely to be inflated.

Analysis of pregnancy rates after rape has suggested that the per-incident rate of conception after rape is higher than consensual pregnancy rates after controlling for birth control use, suggesting that rape has evolved to allow males to spread their genetics (Gottschall and Gottschall 2003). In this study, data were collected from the National Violence Against Women survey, involving a random-digit dialing sample of households in the United States. Participants were considered to be rape victims if they answered yes to the question "Regardless of how long ago it happened, has a man or boy ever made you have sex by using force or threatening to harm you or someone close to you? Just so there is no mistake, by sex we mean putting a penis in your vagina." In

order to help estimate whether pregnancy was a result of a specific rape encounter, women aged 12–45, who had been sexually assaulted one time only, were included in the analysis. Among the 405 women who were eligible for inclusion in the study, 26 reported a pregnancy post rape. When accounting for likely use of hormonal contraceptives, it was estimated that the overall per-incident rape-pregnancy would be 7.98%, which is higher than consensual per-incident pregnancy rates, of around 2–4%. This study suggests that per-incident rape-pregnancy rates are more likely than consensual pregnancies, suggesting rape may give an evolutionary advantage to males who desire to spread their genetic makeup.

Animal Adaptations to Rape

Humans are not the only species in which rape occurs. It is believed that rape occurs in animal species, including bottlenose dolphins and wild-fowl species, for the same reasons as it does in humans, where it is a reproductive tactic to allow males to have a higher chance of successful reproduction. There is evidence to suggest that drake ducks have evolved to allow them to engage in forced copulation (e.g., Brennan et al. 2007). Drake penises have evolved to extend in an anticlockwise motion up to 20 cm in less than half a second and have backward pointing spikes that enable them to stay attached to a female. They also have soft “dusters” which allow the removal of other drake’s sperm.

Therefore, there is evidence that may suggest that rape has evolved as a reproductive tactic in humans, as well as in some animal species. However, regardless of the reasons for rape, rape is undoubtedly costly. Rape can be argued to be particularly costly to females due to the chance of conception with an undesired mate. As sexual assault is highly detrimental on a number of levels, women may have evolved counter adaptations to rape that are inherited in later generations.

For example, despite the apparent adaptation in drakes, which may help to increase the rate of reproduction, only 3% of these forced copulations results in fertilization (Burns et al. 1980). It is

therefore possible that female ducks have evolved their own counter-adaptations to reduce the risk of pregnancy from unwanted copulation. One such counter-adaptation comes from the clockwise direction in which a duck’s vagina spirals. Brennan et al. (2007) found that a drake could project its penis into a straight test tube or one that spirals anticlockwise with ease. However, it was much more difficult to insert into a tube that spiraled clockwise, in the same way that a duck’s vagina does. This creates great difficulty for forced copulation for the drake and suggests that rape as an evolutionary tactic and counter-adaptations to rape go across species. There is also evidence suggestive of female counter-adaptations to rape in water striders (Rowe et al. 1994) and scorpion flies (e.g., Thornhill 1980). However, extrapolation from research on animals to suggest the evolution of a rape adaptation in humans is questionable. As such, to be able to suggest the evolution of a female counter-adaptation to rape, it is also necessary to look at research on humans.

Counter-Adaption Rape Behavior

As well as evidence of female counter-adaptations to rape in animal species, there is evidence to suggest that women may have evolved mechanisms to reduce the likelihood of rape. It is important to note that considering evolutionary perspectives of rape and women’s avoidance of rape in no way justifies this terrible crime and certainly does not shift the blame to victims. Rather, the purpose of this chapter is to provide an overview of the evidence that has been put forward as support for the hypothesis that women may have evolved a counter-adaptation to rape that allows them to maintain their reproductive success and overall fitness. For example, it has been suggested that women appear to behave in certain ways that may reduce their risk of rape. The Rape Avoidance Inventory (RAI; McKibbin et al. 2009) details behaviors women report they would perform to avoid rape. These behaviors fell into 4 broad categories: avoid strange men, avoid appearing sexually receptive, avoid being alone, and be aware of surroundings/

defensive preparedness. Therefore, there appears to be common behaviors that women engage in to potentially reduce the risk of rape.

The Bodyguard Hypothesis (Wilson and Mesnick 1997)

As well as adopting certain behaviors, which may contribute to the avoidance of situations that could result in a rape, it has also been suggested that women have evolved preferences for mates and male friends who can protect them, known as the bodyguard hypothesis (Wilson and Mesnick 1997). This hypothesis proposes that women choose to surround themselves with mates and male friends who are likely to be able to offer protection, through being physically formidable and strong, particularly in high risk places (e.g., in a nightclub or walking at night). Women may choose to surround themselves with strong or intimidating looking males to either intimidate or act as protectors towards potential attackers. However, it is also possible that women may surround themselves with formidable mates and friends because, on average, they are physically weaker compared to men and thus want physical protection in general, rather than specifically as a counter-adaptation to rape. Indeed, women's fear of crime in general is associated with preferences for physically formidable and dominant mates (e.g., Ryder et al. 2016), which may suggest desire for protection is associated with vulnerability more generally, rather than as a mechanism to prevent rape specifically.

Hormonal Influences on Female Counter-Adaptations to Rape

There appear to be hormonal influences on women's counter-adaptations to rape. Although rape is always traumatizing and carries a high cost, there are some situations in which counter-adaptive rape behaviors are also costly to a female as they limit the chances of finding a suitable mate. In order to balance this, it may be that counter-adaptations to rape are particularly active when the costs of rape are considered to be higher,

such as when rape is most likely to result in an unwanted pregnancy. Chance of conception is highest during ovulation and lowest during the early follicular phases. Therefore, although the costs of rape are always high, rape that has a high chance of unwanted conception can be argued to be relatively more harmful to a female's fitness. It may, therefore, be the case that rape avoidance mechanisms are particularly active during ovulation, the phase of the menstrual cycle during which conception is most possible.

Female mate choice is argued to be of primary importance, particularly during the phase of peak fertility, known as the cycle shift hypothesis. A woman's choice of mate is closely related to increasing the chance of reproduction with a male who has strong genetics. In order to increase the chances of reproducing with a male with quality genetics, women find masculine features attractive when they are ovulating compared to the rest of their cycle. For example, while ovulating, females are particularly attracted to males with traits that signal high masculinity, such as masculine symmetric faces (e.g., Penton-Voak et al. 1999). In contrast, women appear to have stable preferences for traits that indicate that a man will likely be a long-term partner who will provide for offspring (e.g., Gangestad et al. 2004). Rape takes away this choice from women and so is particularly costly, especially in regards to unwanted conception.

In brief, the average menstrual cycle lasts from 28 to 35 days. The follicular phase begins on day 1 of menstruation (which on average will last around 5 days) and ends on either day 14 or 15 when ovulation begins. At this point, fertility is highest for women. After this, the luteal phase begins and will usually last until day 28, or until menstruation begins again. Therefore, in summary, conception risk fluctuates over the menstrual cycle and is highest during the ovulatory phase. Although rape is always traumatizing and costly, regardless of menstrual cycle phase, there may be trade-offs associated with rape avoidance behaviors. That is, it could be costly to consistently behave in a way to avoid rape. For example, avoidance of situations of increased risk of rape, such as not going out late at night, could hinder mate-seeking opportunities and chances of

attracting a potential mate. Therefore, mechanisms that may be associated with a female counter adaptation to rape may be particularly prominent when the benefits of these provisions outweigh any costs. Evidence will now be reviewed in support of this theory.

Risk Avoidance Over the Menstrual Cycle

In order to decrease the likelihood of rape during ovulation, it is thought that women will avoid “high risk” situations that increase their risk of rape during the fertile phase of the menstrual cycle. These situations generally include ones in which a woman is alone and vulnerable to an attack by a predatory male.

Research investigating female counter-adaptations to rape across the menstrual cycle was first conducted by Chavanne and Gallup (1998). They tested whether women who were in the ovulatory phase compared to other phases of the menstrual cycle would report having engaged in fewer behaviors that would increase their risk of rape (e.g., letting a stranger into their home, walking in dimly lit areas, going to church). They presented women with a checklist of activities and asked them to indicate the activities that they had participated in during the past 24 h. Participants’ current menstrual cycle phase was measured using the forward count method, which entails estimating the ovulatory window based on the date of a woman’s last menstrual period. Further, each activity had an associated numerical “risk” score, as determined by ratings of rape risk that had been given by a separate group of participants. The activities, thus, could be grouped into high, medium, and low rape risk categories. It was found that naturally cycling women reported having engaged in fewer high risk behaviors if they were in the fertile phase compared to the non-fertile phase of their menstrual cycle. Additionally, women who were using hormone-based contraception had no significant fluctuation across their cycle with respect to risk taking behavior. These results suggest that avoidance of rape-specific risk behaviors may be specific to ovulation when perceived costs of rape may be at their

highest and overshadow the benefits of situations where a suitable mate may be found.

However, Chavanne and Gallup’s (1998) methodology has been critiqued. For example, the validity of the rape risk measurement has been called into question. For instance, women who had engaged in several low risk activities (e.g., staying home to watch a film) could still have an overall risk taking score similar to women who had engaged in a few highly risky activities (e.g., walking home at night down a poorly lit street). In addition, the forward counting method of determining cycle phase is generally considered to be unreliable and inaccurate, particularly when relying on retrospective memories of participants (Bröder and Hohmann 2003). A backward counting approach is preferable; here, participants contact the experimenter on the date when their period begins, and the experimenter can count backwards from that date to determine the ovulatory window. Another limitation is that changes in risk taking behavior as a function of menstrual cycle phase were examined between rather than within subjects. For reasons that have nothing to do with fertility, it is possible that ovulating women as a group were on average more risk-averse compared to their nonfertile counterparts. This made it difficult to understand whether overall, risk taking behaviors truly fluctuated, and thus, in view of these limitations, replication was warranted.

Bröder and Hohmann (2003) sought to replicate Chavanne and Gallup (1998), refining the risk-taking measure. A group of participants rated the riskiness of a range of activities. The 20 highest rated activities were considered risky (e.g., walking alone in a park) and the lowest were considered nonrisky (e.g., speaking on the phone to a friend). In a new sample, women’s menstrual cycle phase was measured within-subjects, and they reported their risk taking during different points of their menstrual cycle. The researchers estimated the stage of menstrual cycle through using both the forward and backward cycling method. They replicated Chavanne and Gallup’s (1998) findings. Risky behaviors were found to decrease during ovulation, while the frequency of engaging in non-risky behaviors remained constant across the cycle.

Thus, the reduction risky behavior cannot be accounted for by a general reduction in activity. However, both Bröder and Hohmann's (2003) and Chavanne and Gallup's (1998) research studies were based solely on self-report. Self-reports of behaviors may also be inaccurate due to retrospective remembering of activities and responding in a socially desirable way. Women may be hesitant to report instances wherein they went out alone, or on a date, for example. Furthermore, risk behaviors in the checklists were limited to instances of stranger rape, without consideration of acquaintance rape, despite being more common (Office for National Statistics 2013).

Both studies are widely reported when discussing adaptations to rape, as they support the bold claim that women avoid situations that heighten their risk of rape, particularly during peak fertility. However, risk behaviors, such as going out alone late at night, could potentially increase one's risk of rape, but at the same time, they also could potentially increase one's chances of meeting a desirable mate. Therefore, perhaps there are mechanisms that allow women to establish when to engage in high risk behavior. Further, perhaps there are other behaviors and cognitions that vary across the menstrual cycle to allow women to control their risk of rape, which will now be reviewed.

Increased Strength

Theoretically, increased physical strength is one possible way in which women may counter their risk of rape. In unwanted sexual scenarios, this would be advantageous as it would allow them to potentially fend off an attacker and avoid rape. Thus, given the high evolutionary cost of rape, increased strength during ovulation may have evolved as a counter-adaptation to rape in women.

To test this hypothesis, Petralia and Gallup (2002) tested whether fertility status influenced strength by gauging women's reactions to sexual assault in relation to their menstrual cycle phase. Women of reproductive age completed a handgrip test to obtain a baseline strength level. After this, they completed a questionnaire regarding the regularity of their menstrual cycle. Participants were

then exposed to one of two brief scenarios. The control scenario described a woman walking to her car in broad daylight in the presence of other people. The sexual assault scenario described a woman walking to her car late at night through a forest while being followed by an unknown man. The scenario ends with the woman beginning to unlock her car door and feeling the unknown man's hand on her shoulder. Participants then carried out two further handgrip and reaction time tasks while being asked to consider the scenario that they had read. Finally, the participants used a urine-based test to estimate menstrual cycle phase.

It was found that there was no difference in baseline handgrip strength as a function of menstrual cycle phase. However, participants who were ovulating and had been exposed to the sexual assault scenario had stronger posttreatment handgrip strength when compared to ovulating women who were exposed to the control scenario. All other groups (i.e., women during phases of lower conception risk or who were using hormonal contraceptives) exhibited a decrease in handgrip strength following the scenario, regardless of the scenario to which they were exposed. Taken together, these results suggest that women's counter-adaptations to rape can be captured in physiology and appear to be most active during ovulation, when the reproductive costs of rape are highest.

Petralia and Gallup (2002) hypothesized that as women in their ovulatory phase are less likely to be raped, there may be a connection between increased strength and rape avoidance. However, other research has suggested that rape is not less frequent during ovulation (Fessler 2003). While Petralia and Gallup (2002) suggested that this finding is representative of the increased ability to thwart off a sexual attack when it would have the most reproductive costs, it is not entirely clear what increased handgrip strength in response to the likelihood of sexual assault occurring was operationalizing. Moreover, while their sexual assault scenario was suggestive of rape, participants may have alternatively thought that the scenario would end in a physical assault or robbery. It may be the case that women increase their risk aversion more generally during ovulation to maximize reproductive success.

Avoidance of Potentially Threatening Males

Other behavioral evidence that women's counter-adaptation to rape may be particularly active during the phase of peak fertility is that of Guéguen (2012), who examined women's avoidance of "strange looking" men. Participants were led to believe they would be participating in a lexical decision task and were asked to take a seat in a waiting room. Participants placed a labial band strip on their tongue, which they believed was to measure cortisol levels. Unbeknownst to the participants, the labial band measured levels of luteinizing hormone to determine menstrual cycle phase. A male confederate, who had been manipulated to appear "shady looking," was also in the waiting room. The investigators were actually interested in determining the location in which women sat while they were waiting. It was found that ovulating women sat significantly further away from the "suspicious looking male" than women who were not ovulating. The investigators concluded that women are more avoidant of "dangerous looking" men around ovulation. This may be indicative of a counter-adaptation to rape. However, there was no control condition wherein a male confederate who did not appear "shady" looking was present in the waiting room. Therefore, it cannot be concluded that fertile women were avoiding the man specifically because of his appearance.

Evaluation of Potential for Coercion

Other researchers have also shown evidence that women may perceive men differently according to their fertility status. One particular counter-adaptation to rape that would be advantageous would be an increased ability to detect the potential for sexual coercion early in an encounter with a man. By so doing, women may be more accurate at detecting a man's actual desires and therefore, will be better able to avoid men who may pose a threat to their fitness. To test this hypothesis, Garver-Apgar et al. (2007) conducted an experiment to test women's perceptions of different

types of men as a function of ovulatory status, which was measured within subjects. They found that women were much more accurate in detecting sexual coercion while ovulating. Furthermore, when participants believed a man to be suspicious, they were likely to overestimate the level of danger he posed to them. Women reported that this strategy enabled them to maximize their ability to avoid dangerous men. Garver-Apgar et al. (2007) suggest that a cognitive error management bias may be the cause of these overestimations. It is less costly to overestimate the likelihood of coercion than to underestimate it.

Garver-Apgar et al. (2007) suggested that it is possible that rather than relating to a counter adaptation to rape specifically, their results may reflect a general increase in fear mid-cycle. However, they contend that fear and anxiety appear to be greater during the luteal phase rather than during ovulation. Previous research does, however, show enhanced sensitivity to fear during ovulation (Pearson and Lewis 2005). Therefore, these findings may reflect an increase in risk perception or fear more generally during ovulation, rather than the counter adaptation to rape being particularly active during ovulation.

Outgroup Evaluation

Women may also differentially avoid outgroup members depending on fertility status. Navarrete and colleagues (Navarrete et al. 2009; McDonald et al. 2011) studied bias towards outgroup members over the menstrual cycle. Outgroup members may have been considered threatening in evolutionary history (Daly and Wilson 1988, as cited in Navarrete et al. 2009), possibly due to the lack of social controls that may be inherent in in-group members. Navarrete et al. (2009) examined attitudes and ratings of attractiveness and "scariness" of outgroup members (as defined by being of a different race) across the menstrual cycle. Women showed higher racial bias, as measured by higher fear and decreased attraction of outgroup members during the phase of peak fertility. McDonald et al. (2011) showed the bias towards outgroup members during ovulation extended beyond race

using an implicit associated test. These findings therefore suggest that women may have a psychological mechanism that increase bias towards men who may be considered threatening with regards to conforming to social norms and thus may be associated with an increased risk of sexual assault, with the bias being emphasized during peak fertility when the costs of rape are arguably the highest. This could be considered as evidence for a counter-adaptation to rape in females, with the mechanism being influenced by hormones.

However, some researchers have suggested that women may be more attracted to outgroup members during peak fertility as a way to increase genetic heterogeneity in offspring (e.g., Marlowe 2004, as cited by Navarrete et al. 2009), which appears contradictory to the findings of Navarrete et al. (2009). Navarrete et al. (2009) suggest further research is necessary to understand the coercion-avoidance versus heterogeneity-attraction processes.

Directions for Future Research

Evidence appears to suggest that women, and some female animals, may have evolved counter-adaptations to rape. Moreover, mechanisms associated with a counter-adaptation to rape in women appear to be particularly active during the phase of peak fertility, which may be due to the relatively higher costs of rape when conception is most possible. For example, women behave in a way that may help to decrease their risk of encountering a sexually aggressive man. However, some research regarding women's behavior over the menstrual cycle may appear contradictory to a female counter-adaptation to rape, and women may behave in ways that could put themselves at greater risk of encountering a sexually aggressive male during ovulation. It is important to note that exploration of the association between menstrual cycle phase and risk of sexual assault in no way justifies violence against women, and it does not shift the blame to the victims.

Ovulating women have been shown to have an increased desire to attend social events where they are more likely to meet men (e.g., a singles mixer, Haselton and Gangestad 2006). Additionally,

research has shown that in order to increase the likelihood of attracting a mate, ovulating women are more likely to dress in a provocative manner (Durante et al. 2008). During ovulation, partnered women become more partial to having sex with unfamiliar men (Gangestad et al. 2005) and were significantly more likely to dance with a male confederate in a nightclub, despite having never met him before (Guéguen 2009). Such situations could increase the chance of encountering a sexual aggressive male and seem to contradict the suggestion that women have evolved a mechanism that works to decrease the risk of rape. Future research should aim to test the relationship between adaptations designed to seek good quality mates at peak fertility while balancing the costs of rape.

Counter-adaptations to rape need to involve assessing the type of male to which they are interacting with, and thus involve complex, but sophisticated mechanisms. In humans, a cognitive error bias may offer a reason as to why women may feel comfortable with strange men in some situations (e.g., Guéguen 2009) and not others (e.g., Guéguen 2012). For example, a nightclub (e.g., Guéguen 2009) is a social place with bouncers who are there to ensure all event goers are safe throughout the night. Women in this context may, therefore, be more accepting towards a strange man who approaches her and will more accurately judge their sexual coercion. However, a woman could meet the same man down a long dark alley, and overestimate the danger posed by the man, and may consider him to be suspicious due to an environment which may feel less safe. Alternatively, the reason may be due to the appearance of the man. In Guéguen (2012), the male confederate was manipulated to appear "shady" and therefore the further distance that ovulating women sat may be avoidance of a potentially threatening male in line with a female counter-adaptation to rape. On the other hand, the male confederates to which ovulating women responded favorably to a romantic gesture from in Guéguen's earlier research (Guéguen 2009) were chosen for their attractiveness. Similarly, while ovulating women showed a desire to dress more provocatively, this was in response to being told they would meet single, attractive males at the

event. Furthermore, while Flowe et al. (2012) found women to show increased engagement with a male during their ovulatory phase, this was only true if the male appeared masculine. In contrast, engagement in nonverbal behavior was relatively lower in ovulating women when the male appeared “shady” (Guéguen 2012). This may represent the fact that women’s behavior has the highest reproductive consequences at peak fertility; they must balance the goals of behaving in a way to both benefit reproductive fitness (e.g., seeking a quality mate) with preventing costs to reproductive fitness (e.g., rape). Future research examining the relationship between attraction versus avoidance of certain males during peak fertility should consider the appearance of the man and setting. For example, having a control condition in Guéguen’s (2012) study wherein there was a male who was manipulated to appear attractive, or neutral, in addition to the condition with the “shady looking” male, may have allowed an understanding of women’s avoidance behaviors over the menstrual cycle.

Are Avoidance Behaviors Specific to Rape, or Risk More Generally?

Women’s avoidance of situations of increased risk of rape may simply reflect danger avoidance more generally rather than a female counter-adaptation to rape specifically. That is, it is not known from previous research whether women are avoiding rape specifically, or are avoidant of all danger and risk in a more general sense, particularly at peak fertility. It is possible that females may be more receptive to any type of danger during ovulation in order to protect their fertility in general. For example, in Petralia and Gallup’s (2002) study on female strength and ovulation in response to risk of sexual assault, the sexual assault scenario did not specifically state that a sexual assault was about to occur and instead left it to the imagination of the female participant. Some participants may, therefore, have thought the scenario was suggesting that a robbery, carjacking, or a physical assault was going to occur. Additionally, the questionnaires used by both

Bröder and Hohmann, and Chavanne and Gallup did not specifically refer to behaviors specific to sexual assault. Although behaviors that are commonly linked to sexual assault appeared on the questionnaires (e.g., walking in dimly lit areas), these behaviors are also closely related to other crime and danger more generally. Therefore, it is unclear whether a risk-averse response from female participants is directly linked to rape-avoidance, or avoidance of danger.

Garver-Apgar et al. (2007) examined domain specificity in women’s perception of male traits over the menstrual cycle and reported that women were more attuned to sexual coercion when ovulating in comparison to other male traits outside of fluctuations in risk avoidance. However, the factors that were assessed as a measure of “sexual coercion” (e.g., creepiness) may also correspond to dangerous males in general. Moreover, bias towards outgroup members (e.g., Navarrete et al. 2009) suggests wariness of potentially threatening men, rather than males who are likely to rape specifically.

In support of the mechanism being domain general over domain specific, there is evidence suggesting that females engage in risk avoidance behaviors during ovulation in situations that are not sexual. Kaighobadi and Stevens (2013) studied the effects of ovulation and risk taking behaviors in women who were gambling. It was found that ovulating women would engage in less impulsive behavior when shown pictures of attractive men while gambling. However, impulsivity did not change when shown a picture of attractive landscapes, or in nonfertile females. Women have also been shown to take less risks in an investment task when ovulating and working with strangers (Ball et al. 2013). Furthermore, females may have an increased response to threatening images in general and have been found to have enhanced detection of faces showing fear (Pearson and Lewis 2005). Similarly, there is neural evidence to suggest that the way in which women process risk may differ depending on their phase of the menstrual cycle. When fertile, women showed increased activation in brain areas associated with risk evaluation when being shown images of typically masculine males, which may

be considered a threat compared to nonfertile women (Rupp et al. 2009). Finally, Šukolová and Sarmány-Schuller (2011) also found that women perceive risk differently according to their fertility status, regardless of what the risk was. It may therefore be that women are more perceptive to risk in general during ovulation, rather than it being an evolutionary adaptation which is specific to rape avoidance.

Taken together, there is evidence to suggest that risky behaviors may be lessened during ovulation in a more general sense, rather than specifically in response to rape. Therefore, evidence suggestive that there is a counter-adaptation to rape, may not apply specifically to women's rape avoidance, but rather their avoidance of risk more generally. Future research should focus on testing for domain specificity through assessing women's responses to the physical versus sexual costs of rape, for example, or through assessing risk aversion over the menstrual cycle more generally. However, researchers should consider the assumptions of the shadow of sexual assault hypothesis (Ferraro 1996) when designing research into female counter adaptations to rape. This hypothesis proposes that women's disproportionate fear of crime in relation to men's and their risk of victimization is due to the assumption that any crime could potentially escalate into a sexual crime. That is, that due to the higher costs (e.g., risk of unwanted conception), women's fear of sexual assault will "shadow" their fear of encountering other types of crime (e.g., robbery). Therefore, it could be difficult to distinguish whether responses are specific to risk of rape, or danger more generally. One suggestion for future research is to assess women's responses to risk and how they vary over the menstrual cycle, in response to danger while controlling for the risk of rape, such as by assessing responses to female-perpetrated crimes. To be able to conclude that ovulatory declines in risky behavior represent an evolved rape-avoidance adaptation to prevent pregnancy resulting from rape, evidence showing "special design" for performing a specific function which cannot be explained with other accounts is necessary.

Conclusion

In summary, women appear to behave in ways that could be suggestive of a female counter-adaptation to rape. For example, female animals have specialized physiology that may prevent forced copulation from males (e.g., Brennan et al. 2007; Rowe et al. 1994; Thornhill 1980). Women also appear to have mechanisms that may be indicative of evolved adaptive traits that could help to reduce the risk of rape, such as avoidance of situations of increased risk of rape (McKibbin et al. 2009) and a preference for mates and male friends who may be able to offer protection (Wilson and Mesnick 1997). What is more, mechanisms that may help to prevent rape appear most active during the phase of peak fertility, when rape arguably poses the highest costs to fitness. For example, during ovulation, women are more avoidant of situations of increased risk of rape (e.g., Chavanne and Gallup 1998; Bröder and Hohmann 2003), show increased strength in response to a scenario suggestive of sexual assault (Petralia and Gallup 2002), overestimate male's sexual coercion (Garver-Apgar et al. 2007), show bias towards outgroup members (Navarette et al. 2009; McDonald et al. 2011), and keep further distance from a male manipulated to appear "shady" (Guéguen 2012). Taken together, these findings appear to support a female counter-adaptation to rape, which is particularly active when conception risk would be highest. However, much of this research is based on self-reports of behavior, which may be inaccurate due to retrospective reporting and errors in remembering, and socially desirable responding on surveys. Moreover, research also suggests that women behave in ways that could potentially increase their chances of encountering a sexually aggressive male (e.g., Guéguen 2009; Durante et al. 2008; Gangestad et al. 2005). Therefore, future research should focus on refining the relationship between balancing mechanisms designed to seek good quality mates at peak fertility and avoiding situations that could potentially be associated with increased risk of rape, with a preferential focus on behavioral, as opposed to self-report methods. Secondly, future

research should consider assessing whether the mechanisms as reviewed above are specific to a female counter-adaptation to rape, or work to protect women from all harm more generally by assessing women's responses to the risk more generally over the menstrual cycle.

Men and women likely evolved different strategies for sexual selection based on the relative time they invested in their offspring (Buss and Schmitt 1993). Male preferences for choosing a mate are primarily based on a female's fertility and reproductive value (Thornhill and Grammer 1999). Men will try to choose a partner whose characteristics signal that she is likely to conceive and who appears to have overall good health (Buss and Schmitt 1993), resulting in women being typically younger in a marriage across societies (Kenrick and Keefe 1992). The signaling that takes place among women is typically done during intersexual competition. Women signal men through verbal and non-verbal means to let men know they are interested in interacting with them (Grammer et al. 2000; Renninger et al. 2004; Wade and Slep 2013; Wade and Feldman 2016), and to get an opportunity to find out about the men's personalities (Grammer et al. 2000).

In order for women to compete intersexually as well as intrasexually, it was adaptive for women to deceive both their rivals and men in order to match the male preferences and obtain an optimal mate (Haselton et al. 2005). Consistent with this reasoning, research has found that women may employ deceptive tactics in order to align with a male's mate preferences.

Previous research discovered that deception typically involved women altering their physical appearance (Tooke and Camire 1991), altering the appearance of their body through behaviors such as wearing facial makeup and exaggerating their hip movements while walking (Tooke and Camire 1991), and withholding their age when writing a personal advertisement for a mate (Pawlowski and Dunbar 1991). Women most frequently report

using intersexual competition tactics that involve altering their physical appearance to exhibit “more” of their physical assets in the hope that such action would elevate a potential male partner’s perception of their physical assets. The women who decide to withhold their age are typically in the 35- to 50-year-old range since older women such as this have lowered fertility and reproductive value. It is adaptive for this group of women to withhold their age in order to obtain a more optimal mate. Also, this type of age withholding deception may be viewed as more passive than active (Pawlowski and Dunbar 1999). Women were found to most frequently report intersexual competition tactics that serve as a strategy for a female to present “more” of her assets in order to alter a potential male partner’s perception of her physical attributes. This alteration of physical appearance is motivated by males’ general preferences for attractive and youthful female partners.

Women may also deceive men about their sexual experiences. In some cases, this is dependent on the current mating strategy (Buss and Schmitt 1993) the women is motivated by. For example, women may downplay their sexual experience because personality traits that signal promiscuity are not desirable for a long-term mate (Buss and Schmitt 1993). Additionally, women may also deceive a male partner about their commission of sexual infidelity. If a woman was to successfully deceive a male by engaging in an extra-pair copulation (EPC), she could increase her fitness since this EPC partner choice diversifies the genetic material of resultant offspring and can lead to the receipt of more paternal investment (Smith 1984). If the woman does not deceive the male partner about her commission of sexual infidelity, she could suffer harm from her male partner, a lower parental investment from him, and mate expulsion as a consequence since he is being cuckolded. Thus, a woman would have to deceive her partner about the commission of any EPCs in order to maintain her current long-term partnership.

So, clearly, deception on the part of a woman is a tactic that includes multiple behavioral strategies that may be used by females to facilitate the chances of finding an optimal mate and keeping an optimal mate.

Female Homosexuality and Bisexuality

Synonyms

Female sexual orientation; Lesbianism; Same-sex sexuality; Sexual fluidity

Definition

Female homosexuality and bisexuality are broad terms that are used to refer to the phenomenon by which women experience sexual attractions and/or pursue sexual behavior with other women. Lesbianism denotes a pattern of exclusive same-sex attractions and behavior, whereas bisexuality refers to a pattern of mixed same-sex and other-sex attractions and behavior.

Introduction

Sexual orientation is generally conceptualized as a stable, trait-like predisposition to experience sexual attractions for the same sex (homosexuality), the other sex (heterosexuality), or both sexes (bisexuality). In the past, the phenomenon of sexual orientation was thought to operate equivalently for men and women, such that female and male homosexuality and bisexuality had similar causes, developmental trajectories, and adult manifestations. Yet scholars no longer think this to be the case. This entry will review some of the most distinctive aspects of female homosexuality and bisexuality and will discuss some of the potential causes for differences between male and female sexual orientation.

Female homosexuality and bisexuality show different patterns of development and expression than male homosexuality and bisexuality. Perhaps most notably, women are more likely to show bisexual patterns of attraction and behavior than

exclusively same-sex patterns of attraction and behavior. One recent review examined the prevalence of exclusive same-sex attractions versus bisexual patterns of attraction in 16 studies published between 2000 and 2016, each of which used a representative probability sample of adults, with sample sizes ranging from several thousand to several million participants (Diamond 2016). These studies consistently found that women were more likely to report bisexual attractions than exclusive same-sex attractions, whereas men were typically more likely to report exclusive same-sex attractions than bisexual attractions. The reasons for this difference between female and male expressions of same-sex and other-sex attractions are not definitively known. This difference might result from a basic sex difference in the phenomenon of sexual desire and arousal, such that women have a stronger fundamental capacity for bisexual sexual desire and arousal than do men. A series of studies examining sex differences in genital responses to sexual stimuli has found support for this view (Chivers et al. 2004, 2007). Specifically, self-identified lesbians and self-identified heterosexuals show similar levels of genital arousal to their preferred sexual stimuli (same sex for lesbians and other sex for heterosexuals) and their non-preferred sexual stimuli (other sex for lesbians and same sex for lesbians). Yet gay-identified and heterosexual-identified men show substantially stronger genital arousal to their preferred sexual stimuli than to their non-preferred sexual stimuli. In essence, these findings suggest that even women who generally experience their sexual attractions as exclusively same sex or exclusively other sex possess a *capacity* for bisexual genital arousal and that this capacity is greater among women than men. Importantly, genital arousal does not always correspond to the subjective psychological experience of sexual desire, and women generally show less correspondence between patterns of genital and psychological arousal than do men (Suschinsky et al. 2009). Hence, women who are capable of becoming genitally aroused to their “non-preferred” gender would not necessarily describe themselves as possessing bisexual attractions or seeking sexual partners of both genders. An additional complication in interpreting women’s patterns of same-sex

and other-sex arousal and desire is the fact that women tend to show more “category-specific” forms of genital arousal (such that lesbian-identified women become specifically aroused to same-sex stimuli and heterosexually identified women become specifically aroused to other-sex stimuli) when they are shown static photos of male or female genitalia, as opposed to videos depicting individuals engaged in sexual activity (Spape et al. 2014). Such findings underscore the difficulty in operationalizing and measuring sexual orientation (Bailey 2009; Chivers and Bailey 2007; Rieger et al. 2005; Savin-Williams 2006). Specifically, is it best conceived as a pattern of sexual arousal (to what specific types of stimuli), a pattern of sexual attraction (to what types of partners and how consistently), or a pattern of sexual behavior (how frequently and under what circumstances)? How should researchers interpret cases in which these patterns conflict with one another? Scholars have not reached consensus on these questions, which makes it particularly difficult to interpret gender differences in such phenomena. For example, if women are more likely to report bisexual patterns of attraction than do men, does this reflect a gender difference in the nature of sexual orientation, a gender difference in social opportunities to express bisexual versus exclusive patterns of same-sex attraction, or a gender difference in the social costs associated with same-sex sexuality? It is likely that all of these factors play some role.

Another distinctive characteristic of female homosexuality and bisexuality concerns the capacity for change over time in sexual attractions and behavior. Although sexual orientation is typically conceptualized as a stable trait, numerous longitudinal studies have found that the specific distribution of an individual’s attractions may shift over time, between exclusive homo-/heterosexuality and bisexuality and vice versa (but rarely between exclusive homosexuality and exclusive heterosexuality). Some studies find that these changes are more common in women than in men, although other studies find similar rates of change in both genders (reviewed in Diamond and Rosky 2016). It is important to note that these changes occur on their own and should not be confused with effortful changes that are sought

in the context of “reparative therapy,” which typically seeks to eliminate same-sex attractions altogether and which has found to be ineffective and psychologically harmful (APA Task Force on Appropriate Therapeutic Responses to Sexual Orientation 2009).

The large-scale longitudinal studies which have documented changes in sexual attractions (usually over the time span of 2–10 years) do not provide any meaningful information about the underlying reasons for these changes. Some interview-based studies of women suggest that entering or exiting certain intimate relationships can facilitate changes in women’s attractions (Diamond 2008), and some scholars have suggested that female sexuality might be intrinsically more “plastic” than men’s (Baumeister 2000). Another possibility is that the phenomenon of sexual “plasticity” or “fluidity” is simply a by-product of women’s propensity for bisexuality. Changes over time between periods of exclusive homo- or heterosexuality and bisexuality are arguably more likely to occur for bisexual individuals, who may sometimes find themselves in environments that foster one “side” of their attractions more than the other (Weinberg et al. 1994). Hence, sexual “fluidity” or “plasticity” may be viewed as a specific form of bisexuality.

In addition to considering the existence of a basic sex difference in the expression of female versus male sexual orientation, it is important to consider the role of social and environmental factors. Extensive research has shown that around the world, women’s sexual behavior and expression has been subject to more social, cultural, familial, and political control than male sexuality (Baumeister and Twenge 2002; Fine 1988). In particular, women have been more seriously penalized than men for deviating from culturally traditional roles as wives and mothers (Faderman 1981; Rich 1980). As a result, women with same-sex attractions may show more variability than men in same-sex attractions and behaviors over the life course, sometimes expressing and sometimes suppressing same-sex desires depending on the characteristics of their local environments (such as opportunities for same-sex relationships and stigmatization of same-sex sexuality) which

may bear on their social and economic livelihood. These factors have also historically operated for men, but arguably with less intensity, given men's greater social power, especially in domains of family and sexuality.

If social and environmental factors have the power to change women's and men's expressions of homosexuality and bisexuality at different points of time and in different social contexts, then one might expect that large-scale historical shifts in the social acceptance of same-sex sexuality should correspond to large-scale historical shifts in the population prevalence of homosexuality and bisexuality. In fact, this appears to be the case and more so for women than for men. Gartrell and colleagues (2012) compared rates of same-sex contact as reported by 17-year-olds in the 2002 and 2011 administrations of the National Survey of Family Growth and found that although the percentage of 17-year-old boys reporting same-sex contact was lower in 2011 (1.4 %) than in 2002 (6.6 %), the percentage of girls reporting same-sex contact was twice as high in 2011 (10 %) as in 2002 (5 %). Twenge and colleagues (2016) examined reports of same-sex behavior across multiple consecutive administrations of the US General Social Survey from 1973 to 2014. They found that the percentage of US adults reporting that they engaged in post-adolescent same-sex sexual contact doubled between 1990 and 2010 (from 4.5 % to 8.2 % among men and from 3.6 % to 8.7 % among women), and these changes were partially – but not exclusively – accounted for by concurrent increases in the social acceptance of same-sex sexuality (Twenge et al. 2015).

Similar findings have emerged from studies conducted in other countries. Mercer and colleagues (2013) examined the prevalence of same-sex attractions in British men and women in three separate administrations of a national probability study. At each administration, over 15,000 men and women were surveyed. Among men, rates of self-reported same-sex attractions were relatively stable across the 30-year period, ranging around 7 % of the population. Yet among women, rates of same-sex attractions increased

from 3.7 % in 1990 to 9.7 % in 1999 and 16 % in 2010). Data collected from the Netherlands shows a similar pattern: Kuyper and colleagues (2009) found that the number of Danish men reporting same-sex attractions from 1989 to 2005 increased from 6 % to 13 % and the number of Danish women reporting same-sex attractions over this period increased even more, from 3 % to 18 %.

The fact that historical changes in the prevalence of same-sex sexuality appear larger among women than among men is consistent with the notion that women's sexuality is more fluid and situation dependent than men's sexuality.

Conclusion

Of all of the presumptions about sexual orientation which researchers have come to question and revise over the years, one of the most important is the presumption that female and male sexual orientation are parallel phenomena, with the same origins and manifestations. Although much work remains to be done in understanding the extent and cause of differences between male and female expressions of same-sex sexuality, scientists now have at their disposal an increasingly reliable body of data charting such differences (reviewed in Diamond 2016). At the present time, the most reliable gender differences concern the prevalence of bisexual versus exclusive patterns of attraction and the propensity for change over time in sexual attractions. Our task now is to determine the bases and reliability of these differences and to understand their implications for models of female and male sexual orientation as well as human sexuality more generally.

Female Hypergamy

► Women Marry Up

Female Infidelity

Christina Bentancourt and Joseph A. Camilleri
Westfield State University,
Westfield, MA, USA

Synonyms

Female extra-pair copulation

Definition

Female who is intimate with someone other than her partner.

Human mating is socially monogamous, where males and females create long-term pair bonds that share space, resources, and responsibilities for raising offspring. Not all such relationships are sexually monogamous, however, because significant proportions of males and females engage in extra-pair copulations. Extra-pair copulations are observed across various fish, bird, mammal, and insect species (Birkhead 2000). In humans, data from the most recent General Social Survey showed that 20% of men and 13% of women report having sex with someone who is not their partner (Wang 2018). Prevalence rates vary across location, sampling, and measurement methods, with some studies reporting female infidelity rates up to 25% (Whisman and Snyder 2007).

Theoretical explanations for the relatively high prevalence rates of female infidelity address its possible functions. Unlike men, women cannot increase offspring number through increasing mate number, but extra-pair copulations may increase female fitness by mating with males with better genes, gaining additional resources, confusing paternity to improve offspring safety, enhancing status, diversifying genes, increasing social networks for employment, or replacing a low-quality mate (reviewed in Mulder and Rauch 2009; Wilson and Daly 1992).

There are two potential factors that increase the risk of female infidelity: female mate value and the amount of time the couple spends apart (Stieglitz et al. 2012). A female's mate value is typically determined by age and her ability to reproduce successfully. Younger females are more likely than older females to be reproductively successful and have higher reproductive value, which makes the potential loss of a younger wife more costly to males. Consistent with this view, Stieglitz et al. (2012) found that women reported their partner experienced more jealousy under these conditions.

Female infidelity may also be costly because of the risks associated with partner jealousy,

including relationship conflict, intimate partner violence, and in some cases, homicide (see ► [“Partner Abuse and Homicide”](#) entry). It appears as though men are more jealous in response to sexual infidelity (i.e., when a partner engages in an extra-pair copulation) than emotional infidelity (i.e., when a partner spends time and resources with someone outside their relationship), since sexual infidelity may result in cuckoldry, which incurs a cost to men. Various sexually coercive behaviors, such as intimate partner sexual and physical violence, may have evolved to prevent or minimize the risk of cuckoldry (Camilleri and Quinsey 2012; Goetz and Shackelford 2006; see ► [“Sperm Competition Risk and Partner Abuse”](#) entry). Considering infidelity is risky and even dangerous, females put great effort in attempt to evade their partner during extra-pair copulation.

Men appear to respond to both direct cues to cuckoldry risk (i.e., by partner's actions that are indicative of infidelity) and indirect cues to cuckoldry risk (i.e., proportion of time spent away from a partner since last having intercourse), where more salient and recent cues are associated with either a greater propensity to engage in either sexual coaxing or sexual coercion (Camilleri and Quinsey 2009).

Female Manipulation of Men

Cassandra Rudd and Joseph A. Camilleri
Westfield State University, Westfield, MA, USA

Introduction

Errors in judgment can either be a false positive (incorrect judgment that something is present) or a false negative (incorrect judgment that something is not present). Error management theory suggests that these overestimation or underestimation errors in judgments or choices may be adaptive (Haselton and Buss 2000) and are sometimes referred to as adaptive biases. In the context of mating, it is possible that females may manipulate particular male biases.

One bias that may be manipulated is men's overperception of female sexual interest (see "Male Sexual Overperception Bias" entry). According to error management theory (see ► "Error Management Theory" entry), it would have been adaptive for men to err on assuming women are sexually interested when they are not, because it would be costly to err on assuming women are not sexually interested when they are. Men, for example, are prone to misperceiving women's friendliness as sexual interest (Abbey 1982). Men, also, will often make advances and may provide some sort of "gift" or attention in order to maintain or enhance her interest (e.g., buying her a drink, dinner, etc.) (Haselton 2003). It is therefore possible that some women may take advantage of men's misperception by accepting resources offered by these men. By using men's own tendency toward making false-positive errors, women can manipulate the way in which men perceive their interest in order to acquire resources (Haselton 2003). For example, women may flirt with and entertain men at a bar even though they have no interest in forming a relationship with

them, sexual or otherwise, because there is a chance he will pay for her expenses.

Women may also use their attractiveness or sexual suggestiveness to manipulate men's mating effort to acquire resources. That is, showing sexual interest manipulates men's interest in indiscriminate sex, motivating men to make some investment to pursue a potential mating opportunity. Although manipulative tactics are generally not sustainable because they incur a cost, tactics that manipulate adaptive errors could be persistent when the benefits of those errors outweigh the costs of being manipulated (Haselton 2003). Also, counteradaptations may evolve in response to manipulative tactics to "exploit the exploiters" (Buss and Duntley 2008). Although the emphasis here is on women's manipulation of men, men may also manipulate women's biases.

Conclusion

Women may manipulate men's overperception of female sexual interest or men's mating effort to gain resources.

Female Mate Choice

Urszula M. Marcinkowska
Jagiellonian University Medical College,
Krakow, Poland

Synonyms

[Females' mating strategies](#); [Women's sexual preferences](#)

Definition

A complex system of conscious and unconscious mechanisms leading to an expression of a preference toward a certain individual or a certain feature.

Introduction

Sex differences in mate choice arise from differences in minimal investment in children between men and women (**minimal parental investment**). For men, basic investment is energy spent for sperm production and then fertilization. For women, not only is the energetic expense for ovum much higher than men's investment in sperm cells, but minimal cost also includes pregnancy and then usually breast-feeding. Due to these primary differences, men and women differ greatly in what they seek in a partner and what choices they make.

Women's mate choice is not fixed throughout their lifetime and depends on a multitude of conditions. Those conditions can be defined as more "internal" (such as hormones or sexual openness) or "external" (e.g., living conditions, family structure, or past sexual experiences). Also due to minimal parental investment inequality, men and women differ in what they want to receive from a partner (putative parent of their future children).

Sex Hormones and Preferences

Women's sex hormones' levels (mostly estradiol and progesterone) vary greatly, both during their lifetime (being highest during fertile years and lower before puberty and after menopause) and monthly (over the menstrual cycle). It is suggested that change in levels of sex hormones influences what women want in a given time of life or month (Anthony C. Little et al. 2010; Penton-Voak et al. 1999). It has also been suggested that women express **dual sexuality** – their preferences and behaviors vary between fertile and non-fertile phases; however, there is an ongoing debate about how strong such menstrual cycle shifts are (for meta-analyses leading to contradictory results on this topic, see Gildersleeve et al. 2013 and Wood et al. 2014).

Mating Context and Relationship Status

Depending on whether women are judging putative partners for a long-term or short-term relationship, they can favor different characteristics. In a long-term relation, parental skills or emotional stability are more sought after. For more of short-term liaison, women direct their attention toward attractiveness (Li and Kenrick 2006) or masculinity and health, manifested through symmetry (Anthony C. Little and Jones 2012). Mating context can change, however, depending on the relationship status of a woman (exerting preference for good genes from a one-time encounter with a masculine man “pays-off” only if a woman is already in a long-term relationship (A. C. Little et al. 2002)).

Sexual Openness

Women's past sexual experience and how easily she enters into physical relationships with emotional engagement play an important role in what she looks for, for example, women who are more sexually open have a stronger preference for masculinity (Sacco et al. 2012) than their more reserved peers.

Living Conditions and Country Characteristics

Mating choices of women also vary depending on the living conditions of their surroundings. Women in countries with worse living conditions show a higher preference toward more masculine men (Brooks et al. 2011; DeBruine et al. 2010), most probably as such men can provide better genes for future children.

Conclusion

Due to differences in minimal investment in children, women are the choosier sex – meaning their preferences will be more complex and expectations will be more stringent than men's when it comes to pairing. Women's characteristics and their life history play an important role in how her mate choices are shaped.

Female Mate Choice (Intersexual Selection)

Anthonieta Looman Mafra
Universidade de São Paulo, São Paulo, Brazil

Synonyms

Women romantic partner choice; Women sexual partner selection

Definition

Romantic or sexual partner selection by women; characteristics that guide female choice of their romantic or sexual partners.

Introduction

Parental investment theory (Trivers 1972) states that male and female have different court behaviors because of the amount each sex invests in offspring. In general, females invest more energy and time in them. This investment becomes even clearer in mammals since gestation and breastfeeding are mandatory for descendants' survival. Because of the energy spent by females, they are limited to a certain number of children they can have and raise. This number depends on several factors such as length of gestation, necessity of taking care of children after birth, and available resources. Thus, females are considered the limiting sex, investing more in parenting effort, while males are known as the competitor sex. For men, greater access to females means a higher probability of increasing their reproductive success, while females' access to resources is a limiting factor for their reproductive success.

Sexual Strategies Theory

Buss and Schmitt (1993) noticed that men and women have a different pattern of choosing their romantic partners. Natural selection has acted on both sexes behavior and modulated their mate preferences in order to maximize individuals' reproductive success.

Women have 9 months of gestation, at least 6 months of breastfeeding and the primary care with children. Due to this high investment in offspring, a mate who helps her with protection against predators and rivals and provides resources to her and their offspring increases the possibility of survival and tends to be considered more attractive (Buss 1989; Buss and Schmitt 1993).

Long-Term Relationship Preferences

According to the evolutionary perspective, women who chose a partner that could provide protection and resources to them and their offspring had greater reproductive success. Due to females' high investment in children, they tend to be more selective than males when looking for their romantic partners and to prioritize long-term relationships. In order to help her to raise children, a man needs to establish a commitment with her. Because of that, they also look for a partner who is willing to invest in them and in their offspring, which may be observed through traits like faithfulness and commitment (Buss 2003). Besides being committed, being faithful assures women that her partner invests in her and their offspring, decreasing the risk of having to share his resources and time with another woman and her family.

Environmental Influence on Females' Mate Choice

In general, women tend to invest more in long-term relationships and choose their partners accordingly, as aforementioned. Such strategy and preferences may change, however, depending on the environment.

Gangestad and Simpson (2000) claimed that women change their strategies according to environmental features, such as pathogens' level and amount of resources available. In general, women prefer a partner with high socioeconomic status, as predicted by the sexual strategies theory. Nevertheless, it occurs in an environment where pathogens' levels are not too high or when biparental care is important for children survival. In high pathogens' levels environment, women face another problem: assurance of good genes, a good immunological system in order to survive. For this matter, they no longer use a long-term strategy. Instead, they tend to choose a partner who is physically attractive. Physical attractiveness is related to the good capacity to protecting the human body against pathogens. Body and facial symmetries, for example, gives men and

women clues about their pathogens' history. A symmetrical person indicates that she or he had enough energy in the childhood to develop their body symmetrically at the same time their immunological system was fighting against external and internal agents (Pawlowski 2000; Thornhill and Gangestad 1993). A woman who chooses a more attractive partner, in a harsh environment, tend to have children both more physically attractive and with better pathogens resistance, increasing their capacity of survival and procreate, and consequently, higher probability of increasing women's reproductive success (Gangestad and Simpson 2000).

Menstrual Cycle

Besides environmental conditions, women's mate choice can suffer influence of other factors, such as menstrual cycle. Women who do not take contraceptive pills tend to rather more masculine men when they are in the most fertile phase, while women who were in other phases (luteal phase, for example) found more attractive as a romantic partner men that have more feminine traits (Jones et al. 2008). Men with more masculine faces, bodies, and voices, in general, have higher testosterone levels and are considered also as more aggressive, unfaithful, prone to engage in more risky behaviors, having a higher number of sexual partners, and less prone to engage in a long-term relationship. These men, at the same time that signal good genes, signal less probability of invest in them and in their children. However, men with more masculine characteristics are good partners to have a short-term relationship with, increasing the change of successful pregnancy, and to provide good genes to their children when women are most fertile (Jones et al. 2008).

Conclusion

Due to the high investment (energetic, physiological, and in time) women make in children, they tend to choose a partner who can help them with their offspring, investing with resources and being

committed to them. However, the environment also modulates females' mate choice. In harsh conditions, they may change her mate preferences in order to maximize their reproductive success, investing more in short-term relationships and preferring characteristics that indicate good immunologic system quality, such as physical attractiveness, instead of resources.

Definition

Female mimics are males of otherwise sexually dimorphic species that resemble females in appearance and behavior.

Introduction

In sexually dimorphic species, some males will look more like females than males when it comes to size, coloration, pheromone signaling, and behavior. Such female mimics are widespread across the animal kingdom; they have been described in beetles, ants, mollusks, crustaceans, and every vertebrate class, among others (Oliveira

et al. 2008). Taking up the female appearance can be permanent or temporary. In the majority of cases it is a form of deceit to gain competitive advantages, for example, female mimicry is used as an alternative mating strategy by smaller males who otherwise would not be able to mate. In their disguise, the sneaker male can approach females and avoid agonistic interactions by the larger males and frequently manages to steal copulations.

Alternative Mating Strategies

In species with strong sexual selection, matings are often monopolized by very few dominant males. To become dominant, a male typically needs to be large and aggressive. Under these circumstances smaller males hardly ever have the chance to mate. Female mimicry is an alternative mating strategy that enables some males to gain reproductive success. Disguised as a female these males are often not detected by their dominant rivals and can hence avoid aggressive confrontations and eviction from the territory and stay in close proximity of receptive females that have been attracted to the dominant male. Whether females choose to mate with the sneaker male or cannot avoid the sneaky copulation when attempting to mate with the dominant male is unclear, although the current evidence points towards a preference for the dominant males and female avoidance of sneakers where possible (Oliveira et al. 2008).

The sneaker male will mimic females in many morphological and physiological traits, coloration, and behavior. Pretending to be a female is not restricted to visual effects. In the tropical ant *Cardiocondyla obscurior* the sneaker male mimics the queen's chemical bouquet to avoid fights with aggressive males that otherwise often lead to death (Cremer et al. 2002). This chemical mimicry is effective in competition for matings with virgin queens in the nest, which otherwise would be monopolized by the aggressive males. Sneaking behavior and female mimics also have hormonal adaptations; for instance the mimics often have lower levels of testosterone, which is

associated with aggressive behavior, than the ordinary males (Cardwell and Liley 1991; Sinervo et al. 2000; Küpper et al. 2016). Female mimics do not express typical male ornaments, nevertheless he always possesses male gonads. The testes of sneaker males are occasionally larger than those of dominant males and may increase its chances of siring offspring during sperm competition (Küpper et al. 2016).

Female mimics have two principal behavioral tactics. They may either try to avoid the attention of the dominant male or stealthily sneak copulation when the dominant male is engaged otherwise. Alternatively, they may actively distract the dominant male from copulations by posing as a receptive female and drawing attention away from the female to themselves. This deceit is very effective and the mimic is frequently mounted by the male who will then waste time, sperm, and energy on the female impersonator.

As other alternative mating strategies, female mimicry is often under negative frequency dependent selection since the deceit is most effective when mimics are rare within a population. By enabling more males to participate in reproduction it reduces the reproductive skew within a population.

Permanent Versus Temporary Female Impersonation

Female mimicry can be expressed permanently or temporary by males. Permanent mimicry is known to have a genetic basis in birds and crustaceans. In the Ruff *Philomachus pugnax*, the genes responsible for the female mimicry are located within a chromosomal inversion (Küpper et al. 2016). A genetic basis, however, does not necessarily mean that female mimicry is expressed life-long. In the common Side-blotched Lizard *Uta stansburiana*, female mimics can develop into monogamous territorial males that have higher fitness when the frequency of the sneaker male is high (Sinervo et al. 2000). Temporary female mimics occur in some fish. In the Stoplight Parrotfish *Sparisoma viride*, individuals change their sex from female to male throughout

their lifetime. Large size is required for males to successfully defend a territory and therefore fish start off as a female and become males only once they have grown to the appropriate size. Some male parrotfish maintain the female phenotype despite having already developed male gonads. These males then live temporarily as sneakers on the territories of dominant males until they have grown enough to become a competitive territorial male (Cardwell and Liley 1991). In Pied Flycatchers *Ficedula hypoleuca*, second year males often retain the juvenile/female plumage since in this disguise they are tolerated by older males and not recognized as competitors, which provides them with advantages in conflicts over resources (Sætre and Slagsvold 1996). Sneaker males of the Giant Cuttlefish *Sepia apama* can actively change between male and female appearance and behavior within seconds (Hanlon et al. 2005). An example for extreme flexibility is provided by the Mourning Cuttlefish *Sepia plangon*, where some males have been observed to take up female coloration and patterning only for the parts of his body that is exposed to a male competitor while simultaneously displaying as a male to a female with the other side of its body (Brown et al. 2012).

Other Contexts

Female mimicry also occurs in nonbreeding context. Male garter snakes that recently woke up from hibernation in spring produce female pheromones to attract other males. Within the resulting male aggregation the mimics can avoid predation better and increase their own body temperature and hence become mobile quicker (Shine et al. 2001).

Conclusion

Female mimicry is an effective deceit strategy of males that is often found in populations with high sexual selection and strong reproductive skew. It increases the fitness of males that otherwise would not be able to mate but is most effective when rare. Female mimics usually don't display to females and can be seen as reproductive parasites of

territorial males that dominate male-male competition. Through morphological, physiological, and behavioral adaptations mimicry increases phenotypic variation.

Introduction

Evolutionary analyses of human behavior characterize modern phenotypes as potential products of natural and sexual selection. Within evolutionary psychology, the human female orgasm generates debate as to an adaptive function because, compared to male orgasm and ejaculation, it is not required for fertilization (e.g., Lloyd 2009 and Puts and Dawood 2006). Evolutionary researchers have proposed two main theories offering adaptive explanations for the female orgasm (Puts et al. 2012a). These Mate-Choice Hypotheses argue that female orgasm increases the probability of producing offspring, thereby falling within the purview of natural selection. Of these adaptive hypotheses, the Pair-Bond Hypothesis would increase survival of offspring through women's selection of long-term mates, while the Sire Choice Hypothesis focuses on orgasm's potential to increase genetic quality of offspring through women's selection of high-quality mates. We describe these models to frame current research on the relations among human female orgasm and in-pair copulation.

Female Orgasm and Conception

Several authors have described in detail the physiological mechanisms that could increase correspondence between women's orgasm and fertilization (e.g., Welling 2014). Briefly, female

orgasm increases the probability of conception via oxytocin release and subsequent uterine contractions that favor fertilization (Puts et al. 2012a). Furthermore, women are more likely to experience orgasm when fertile (Udry and Morris 1968), and the mechanical process of orgasm increases sperm retention in the vaginal canal (Baker and Bellis 1993; cf. Lloyd 2009). Interestingly, when oxytocin stimulates uterine contractions during the fertile phase of the menstrual cycle, fluid transport is directed to the fallopian tube of the dominant follicle which increases the probability of pregnancy (Wildt et al. 1998; Zervomanolakis et al. 2007). In comparison, during non-fertile phases, fluid is transported to both fallopian tubes.

Pair-Bonding

The Pair-Bond Hypothesis states that the survival of our large-brained offspring was dependent on investment from the male; one female alone would not have been able to provide all the necessary care to a helpless, immobile infant (Fisher 2004). Purportedly, a woman who could procure investment from a male would be more likely to survive, as would her offspring. The Pair-Bond Hypothesis stipulates that were a female to forge an affectionate and monogamous bond with her mate – and, critically, signal paternity certainty that he might otherwise lack – she would be able to receive long-term investment and cooperative parenting (Ellsworth and Bailey 2013; Fletcher et al. 2015; Wheatley and Puts 2015). Her orgasm frequency might encourage her to remain with one partner who could provide repeated pleasure, and feelings of calm and trust (Acevedo 2015; Zak et al. 2004). Each time a female orgasms, a multitude of feel-good chemicals – oxytocin, dopamine, and serotonin – are released in the body, solidifying the bond and promoting feelings of love and reward-seeking behavior (Fisher 2004; Thornhill and Gangestad 1996). This, of course, supposes that her male partner has prosocial qualities, such as empathy, with a vested interest in his partner's pleasure (Kennedy and Pavlicev 2018). His altruistic interest in her pleasure could serve as a means to prevent infidelity (Kennedy and Pavlicev 2018; Welling 2014; Wheatley and Puts 2015).

Penile-vaginal orgasm occurrence in relationships is associated with intimacy, satisfaction, and passion (Costa and Brody 2007), supporting the idea that orgasm occurs in the presence of an intimate bond. Relationship length and happiness also correlate positively with orgasm frequency (Eschler 2004; Gebhard 1966), and women have been reported to seek out long-term sexual relationships, rather than short ones, unlike their male counterparts (Clark and Hatfield 1989; however, see also Hald and Høgh-Olesen 2010). Eschler (2004) surveyed 202 women about their sexual behaviors and discovered that women are motivated to remain in relationships in which they achieve orgasm. Over three-quarters reported that reaching orgasm with their sexual partner was “very” or “somewhat” important, while only 1% stated it was “very unimportant.” The women also reported that their level of enjoyment during sex was heavily influenced by whether or not they had an orgasm. In a later replication of this work, two-thirds of female respondents ($n = 274$) were extremely satisfied in their relationships, whether short or long term, when they experienced orgasm, while only 6% were satisfied in relationships in which they never had an orgasm (Patch et al. [In preparation](#)). On the other hand, some studies have indicated that individuals in monogamous relationships report lower levels of satisfaction and have sex less frequently than those in nonmonogamous relationships (Conley et al. 2018). The authors suggested relative sexual satisfaction in monogamous versus nonmonogamous couples may reflect differences in the amount of effort or time placed upon cultivating an exciting sex life (Conley et al. 2018).

Partnered males who are more satisfied in their relationships report greater interest in their partner’s ability to achieve copulatory orgasm (Welling 2014). If orgasm is important to forming and sustaining bonds, individuals might be tempted to fake an orgasm. Although both men and women report having pretended orgasm, sex differences exist in their reasons for doing so. Among women, feigning orgasms is more likely when they perceive higher risk of partner

infidelity and as part of a larger mate retention strategy (Kaighobadi et al. 2012). Feigning orgasm in these contexts would generally support relationship maintenance and are consistent data showing women report higher interest and persistence in ensuring partner orgasm than men (Barnett et al. 2018). In contrast, Ellsworth and Bailey (2013) reported that females who were more likely to fake an orgasm were also more likely to engage in extra-pair copulations and, additionally, that a male’s perception of their partner’s fidelity was not predicted by orgasm occurrence. These two pieces together weaken support for the pair-bonding hypothesis, which places importance on a male’s accurate detection of their partner’s orgasm.

If female orgasm evolved to support pair-bonding, we might expect differences in orgasm frequency in females who are less likely to form attachments. Females with avoidant attachment style are more likely to report less enjoyment from sex and low satisfaction in intimate relationships, which might reduce orgasm frequency (Cohen and Belsky 2008). Women with avoidant attachment styles were less likely to achieve orgasm and were also less likely to be in a relationship, while anxious attachment was not significantly correlated with orgasm frequency (Cohen and Belsky 2008; Patch et al. [In preparation](#)).

Sire Choice

The Sire Choice Hypothesis predicts higher rates of orgasm with high-quality mates whose phenotypic quality correlates with genotypic quality. This perspective explains the variation in women’s coital orgasm experience as reflecting greater choosiness in mates. Specifically, researchers employing an evolutionary lens propose that lower frequency and greater complexity involved for women to achieve orgasm reflect selective mate choice, presumably in favor of mates with higher-quality characteristics (Wheatley and Puts 2015). This perspective is supported by research reporting lower frequencies of orgasm among women and data indicating that orgasm frequency increases with high-quality mates. For example, Lloyd (2009) reports that just 25% report always

experiencing coital orgasm and about 60% reporting orgasm most of the time.

With regard to orgasm with high-quality mates, prior research has demonstrated associations of coital orgasm with mates who were physically attractive (Gallup et al. 2014; Puts et al. 2012b; Shackelford et al. 2000), symmetrical (Thornhill et al. 1995), and more masculine (Puts et al. 2012a) and had relatively dissimilar genes in the major histocompatibility complex (MHC) region of the genome (Garver-Apgar et al. 2006; see also Black and Cabeza de Baca 2018). One study found that women reported more orgasms with wealthy partners (Pollet and Nettle 2009), but follow-up research found these results were confounded by differences in women who partner with higher-income partners. Specifically, women with high-income partners were younger, healthier, happier, and better educated than women with lower-income partners (Herberich et al. 2010; Pollet and Nettle 2010). Still, more recent research found that women's orgasm frequency was positively associated with the partner's family income (Gallup et al. 2014). Furthermore, several studies have shown increased preference for these traits near ovulation (e.g., Gangestad et al. 2004; Little et al. 2011; Puts 2006). Taken together, these findings support sex-specific adaptation of the female orgasm.

Although these data are strongly suggestive of a gene capture strategy, other studies show that women's orgasms are more frequent within long-term relationships (Armstrong et al. 2012; Eschler 2004; Patch et al. *In preparation*). Inferences about Mate-Choice Hypotheses in this case are challenging, as analyses involving both high-quality mate characteristics and relationship duration show mixed findings. For example, Shackelford et al. (2000) found that only partner attractiveness predicted orgasm in regression models that included duration of relationship. Puts et al. (2012a) found relationship duration predicted women's orgasm during or after men's orgasm, but not before men's orgasm. Prior research indicates that vaginal contractions associated with women's orgasm may accelerate male ejaculation (Meston et al. 2004). Furthermore, when women's orgasm occurs within 1 minute

prior to (and up to 45 min after) male ejaculation, sperm retention increases (Baker and Bellis 1993). In light of these findings, women's increased orgasm prior to men's orgasm, which is associated with male masculinity and dominance (but not relationship duration), may be less likely to result in conception. In contrast, both the man's attractiveness and couple relationship duration predicted women's orgasm during and after men's orgasm, which more closely maps on to the period in which increased conception is likely.

Further challenges to the Sire Choice Hypothesis include data from Sherlock et al. (2016) which found support for partner attractiveness increasing orgasm, but not masculinity, dominance, or fitness as found in previous studies. Gallup et al. (2018) offer alternative explanations for absent but expected effects according to Sire Choice, suggesting that the methodology used may have limited partner fitness in the sample, since women were asked to report on their current partner and one with which they had the most orgasms. Still, it is fairly common for existing research on women's orgasm to ask women to reflect on a current or past partner, so similar criticisms could be lodged against those studies as well.

Another study examined whether women's partner characteristics predicted orgasm by distinguishing "surface" and "deep" orgasms, which roughly mapped on to clitoral and vaginal orgasms, respectively (King and Belsky 2012). Deep orgasm, they argued, is more likely to produce physiological changes to increase the probability of conception compared to surface orgasm. Their results showed deep orgasm was associated with higher attractiveness of partner's smell, dominance, and considerateness, but not partner's masculinity, muscularity, or aggressiveness. However, further research confirming their proposed physiological differences between these two types of orgasm is necessary to fully interpret their findings within an adaptive framework.

High mate value males may be less likely to invest in partners (Gangestad and Simpson 2000), so this gene capture strategy may manifest in shorter-term sexual relationships or extra-pair relationships (Gangestad and Thornhill 1997).

However, studies have documented that, compared to men, women experience fewer orgasms during one-night stands (Eschler 2004) and first-time hookups (Armstrong et al. 2009). Some have proposed that the orgasm disparity may partially be explained by gender role socialization that promotes male sexual pleasure while criticizing women's sexuality (e.g., Armstrong et al. 2009). Others have highlighted individual differences, such as sociosexuality. Women with unrestricted perspectives of casual sex report having had orgasms with their last short-term sex partner (Armstrong et al. 2012). Among women who have engaged in extra-pair copulation, more frequent coital orgasms occur with extra-pair mates compared to in-pair mates (Baker and Bellis 1993; Gallup et al. 2006). Their extra-pair partners have low fluctuating asymmetry (Gangestad and Thornhill 1997).

Critiques of Adaptive Perspectives

By-product Hypothesis

The By-product Hypothesis suggests that female orgasm results from shared ontogeny with men and serves no adaptive function. Male nipples represent other human phenotypic traits that are thought to be products of shared developmental processes (Symons 1979). When traits are strongly selected in one sex, then, the opposite sex may retain similar but diminished versions of these phenotypic features. However, it should be noted that traits initially produced as by-products at one point may develop an adaptive function under different circumstances when they become correlated with reproductive success.

Puts et al. (2012a) note that the female orgasm does not appear to be diminished relative to male orgasm, contradicting the By-product Hypothesis. Rather, female orgasm may be more psychologically intense, and women are more likely to report experiencing multiple orgasms compared to men. Zietsch and Santtila (2011) tested the By-product Hypothesis, arguing that if true, male and female relatives should show similar patterns in orgasmic sensitivity. Analyzing data from monozygotic and dizygotic twins and non-twin siblings, Zietsch

and Santtila compared ease of achieving orgasm and showed no positive associations among opposite-sex sibling pairs. Although these data fail to support the By-product Hypothesis, they do not rule out the possibility that selection pressures favoring male orgasm have produced species-wide genotypes that influence orgasm.

While early arguments for the By-product Hypothesis suggest that female orgasm is too inconsistent to be associated with an adaptive function (Symons 1979), proponents of evolutionary models argue that women's selectiveness about mates (Trivers 1972) also applies to female orgasm (Puts and Dawood 2006; Puts et al. 2012a). In summary, while this hypothesis provides sound evidence in some respects, there have been and continue to be critiques of the By-product Hypothesis.

Limitations of Evolutionary Evidence

Studies testing evolutionary hypotheses about female orgasm often operate under assumptions that the female orgasm is easily identifiable by sexual partners, the female orgasm is derived from and similar to male orgasms, and sexual intercourse evokes the same response in both males and females (Lloyd 2009). While it is reasonable to test specific hypotheses, it should be noted that evolutionary assumptions restrict the focus of hypotheses, data collected, and conclusions drawn. For instance, evolutionary hypotheses focus on sexual encounters as they relate to reproduction; however, human sexuality is a multifaceted phenomenon not always manifested under circumstances that could produce offspring.

Second, the literature shows conflicting evidence on several of the key relationships identified by evolutionary researchers. As an example, one study examined women's orgasm characteristics (frequency, method, and behaviors) and characteristics of male partners with which orgasm occurred (Sherlock et al. 2016). Only some traits predicted by evolutionary hypotheses were significantly associated with women's orgasm. Specifically, creativity, attractiveness, humor, emotional warmth, faithfulness, and body odor pleasantness were greater in high-orgasm partners (Sherlock et al. 2016).

Additionally, high-orgasm partners scored highly on behaviors such as communication, use of sex toys, oral sex, foreplay duration, and clitoral stimulation (Sherlock et al. 2016). While these results are consistent with some previous studies, the results fail to show differences between high- and low-orgasm partners on the basis of relationship length and traits such as intelligence, dominance, athleticism, muscularity, fitness, earning potential, and height and weight – each of which is predicted or demonstrated in prior evolutionary research.

How Women Achieve Orgasm

Gebhard and colleagues found 84% of female orgasms achieved through masturbation were derived through the stimulation of the clitoris and the labia, and less than one-fifth of women orgasm by penetration of the vagina, but the majority of those women who do, also accompany penetration with clitoral stimulation (Gebhard et al. 1970, p.15; Lloyd 2009, p. 111). Studies on the female orgasm offer data which provide that the number of females who orgasm by penetrative intercourse unassisted by clitoral stimulation is fairly low – less than 35% (Eschler 2004; Lloyd 2009; Wallen 2006; Welling 2014). If the female orgasm served strictly a reproductive function, one would expect women to orgasm more through coitus, rather than the commonly reported higher frequency of orgasm through stimulation of the vulva and clitoris.

Metascientific Critiques

Perhaps one of the most increasingly argued critiques of evolutionary models of female orgasm involves the androcentric point of view which has largely generated and interpreted the data to date. Several evolutionary biologists have discussed how female orgasm and sexual experiences are framed within the literature, such as orienting women's orgasm around men's sexual experiences (e.g., Hrdy 1979; McClintock 1981). Wasser and Waterhouse (1983) compiled a list of claims regarding female phenomena, including the following regarding female orgasm: “the female orgasm evolved to make women quiescent following copulations so as to prevent the male's sperm

from leaking out of the vagina (Morris 1967); the female orgasm evolved as a ‘byproduct’ of selection for male orgasm” (Symons 1979).

In our review of literature on women's sexuality and orgasm experiences, we noted similar sentiments. Wheatley and Puts (2015) argue that clitoral and vaginal orgasms are produced through stimulation of the same underlying structures, partly due to the expanding structure of the clitoris, which includes the bulbs, corpora, and crura, and attachments among these structures by connective tissues in the mons pubis, labia, urethra, and vagina. They conclude that, in contrast with several studies that show women distinguish between vaginal and clitoral orgasms (Brody and Weiss 2010; King and Belsky 2012; King et al. 2011), “women may be unable to reliably differentiate clitorally- and vaginally-induced orgasms” (p. 126) on the basis of one study with 38 participants and a second study that which in actually showed women were able to distinguish between clitoral and vaginal orgasms (Clifford 1978; Prause 2011). While we agree with Wheatley and Puts (2015) that physiological measures of these different experiences would contribute to the field, we disagree with the notion that extant research is “insufficient” evidence for distinct kinds of orgasm.

Another involves research investigating the female G-spot, stating, “Why then do some women have difficulties achieving vaginal orgasm if every woman supposedly had the equivalent of a penis?”, referencing the clitoral complex (p. 1223, Foldes and Buisson 2009). It is difficult to find a place to start offering clarification to these authors, but this quote is illustrative of numerous papers on women's sexuality citing women's reports on their sexual experiences, but nevertheless with the subtext, “What do women want?”

This is perhaps not surprising, as “most researchers have historically been males, or at least trained in the ‘male tradition,’ [which] has resulted in a disproportionately large amount of behavioral research on vertebrates that is focused predominantly on males” (p. 19, Wasser and Waterhouse 1983). Thus, we echo the sentiments of Wasser and Waterhouse (1983) who acknowledge that “our poor understanding of female

behavior, and hence needs has already detrimentally affected health care...education... and economic quality among women, as well as caused us to sidestep the importance of a number of female psychological...and physiological processes.” And, while we too do not intend to critique previous researchers themselves, we think it is worth noting in our review, 26 years after the publication of *Social Behavior of Female Vertebrates* (Wasser 1983), we found that, still, most of the researchers publishing on female orgasm, who often couch the phenomenon only with reference to its role in heterosexual intercourse, do so in an androcentric way.

Conclusion

We described and presented evidence offering explanations for women’s orgasm experiences in the context of in-pair copulation, using By-product, Pair-Bond, and Sire Choice Hypotheses as frameworks. The By-product Hypothesis is unlike evolutionary theories of the female orgasm because it does not suggest that the human female orgasm is purposeful for reproductive success. In contrast, Mate-Choice Hypotheses, which include Pair-Bonding and Sire Choice, are well-known evolutionary theories of the female orgasm which propose functionality or support for reproductive success. This review finds that several studies fail to support the By-product Hypothesis (see Puts et al. 2012a for a summary). While the Pair-Bond and Sire Choice Hypotheses have been presented as alternative explanations for women’s orgasm in relationships, it is possible that coital female orgasms reflect allocation of resources toward both obtaining mates’ long-term investment and high-quality genes (Wheatley and Puts 2015).

Furthermore, the focus on in-pair copulations neglects findings from a variety of studies focusing on individual differences that contribute to women’s orgasm experiences. These include genetic influences (Dawood et al. 2005; Zietsch and Santilla 2011), life history strategies (Gallup et al. 2014; Patch et al. *In preparation*; however, cf. Zietsch et al. 2011), attachment (Costa and Brody 2011); psychological maturity (Brody

et al. 2011), and personality (Harris et al. 2008). It is also beyond the scope of this entry to discuss at any meaningful length women’s orgasms during nonreproductive activities such as masturbation, in nonheterosexual relationships or in nonmonogamous relationships. Nor can we provide adequate discussion of the impact of gender role socialization and sexual double standards that contribute to the orgasm disparity among men and women. Thus, although we have described research applying evolutionary perspectives, it should be noted that a thorough analysis of female orgasm would benefit from a broader lens.

Female Reproductive Variance

Mark McCoy¹ and Patrick Nebel²

Synonyms

Female choice; Parental investment theory; Reproductive variance; Sexual selection

Definition

The degree to which sexual selection pressures female members of a species. Female reproductive

variance is tied to the fertility of the individual and less to their ability to mate and reproduce. Hence, female reproductive variance is quite low relative to male reproductive variance.

Introduction

Research has found a pattern of reproductive variance for many species in which females have far less variability in their reproductive output than males. Three factors contribute to the pattern of mating behaviors that are typical for females: most females successfully reproduce, the amount of copulations shows a weak relationship with the number of offspring for females, and for many species, females have a greater minimum obligate investment to produce viable offspring.

Female Reproductive Variance

Angus Bateman is among the first to formally study reproductive variance. In 1948, Bateman tracked the reproductive output of male and female fruit flies (*Drosophila melanogaster*) (Bateman 1948). Bateman made two important observations regarding sex differences. First, very few females failed to successfully mate (about 4%), while a much larger proportion of males failed to reproduce. Second, the reproductive output of females showed a much weaker relationship with the number of copulations than for males. Based on these observations, Angus Bateman articulated what would be known as Bateman's principle: reproductive variance is greater for males than for females.

This relationship has been found consistently across a wide range of species. Among humans, the majority of women who are able to produce offspring will be able to, assuming they have the desire to do so. Additionally, the maximum amount of offspring a woman can birth in her lifespan is highly limited, practically not much more than 12 (Buss 2014).

According to Robert Trivers' parental investment theory, females, among most vertebrate species, have a greater minimum obligate investment

in the production of offspring (Trivers 1972). This is largely accounted for by the anisogamy of male and female gametes as well as the burden of internal gestation. Due to this higher minimum investment in offspring, Trivers proposed that females adopt a mating strategy based on being highly selective and "choosy" when assessing potential partners and mating opportunities. Put another way, because reproductive output is much more constrained for females, a more viable strategy is to focus on quality of mating opportunities rather than quantity.

It is important to note that there are species that do not conform to this pattern of behavior, however. The phalarope is a genus consisting of three species of shore birds known for having sex-reversed roles (Colwell 1986). These species engage in polyandry in which females are larger with more coloration and compete for mates, while males incubate and provide primary care for the offspring. These exceptions to the rule can be explained by factors such as operational sex ratio (Colwell and Oring 1988).

Conclusion

There is a pattern across many species where the females will adopt a mating strategy of being highly selective of mates. Although this strategy is not found among all species, the prevalence of this strategy can be largely attributed to the lower reproductive variance that often characterizes the females of a species as well as the greater minimum obligate investment that females of most species must endure in order to produce viable offspring.

Female Sneak Copulation

James Malcolm Howie and Andrew Pomiankowski
University College London, London, UK

Synonyms

Sneaky mating; Undetected extra-pair copulation

Definition

Undetected copulation with the partner of another female or in defiance of the dominant female; often punished if detected.

Introduction

A female sits with her partner, or with a dominant male. She is able to reproduce and benefits due to her partner's parental care and protection. Another female – of low rank, in a female-driven dominance hierarchy – has failed to find a partner and has yet to mate. In each case, the female can increase her reproductive fitness by mating with an additional male, with additional males, or by mating for the first time. But in order to do so, she must overcome various forms of resistance. In the first case, the partner of the female, or the dominant male, will not want her to “cheat” on him. Likewise, the partners of her additional mates will not want “their” males to cheat on them. Finally, in the case of the low-rank female, a dominant female will not want her to win over reproductive access, because this could lead to a dilution of the benefits that she receives both in terms of parental care and protection.

Here then is the basis for two broad forms of female sneak copulation (FSC). One is based on a partnered female's attempt to “have her cake and eat it”, in which she tries to obtain the benefits of additional mates – such as additional parental care or genetically diverse offspring – while also attempting to avoid the costs of discovery, which are likely to result in lower parental investment by her partner or even physical punishment. Another arises when a female attempts to break rank, to the same end but with different risks. Yet cut across these two forms is another division. In the case of the partnered female, the punishment (i.e., fitness loss) is meted out not only by the male partner but also by the *female* partners of her additional mates. In the case of the low-rank female, the punishment is administered by the dominant *female*. The rest of this section focuses on these female-female interactions linked to female sneak copulation (FSC), where a female tries to ensure additional, secretive reproduction, in defiance of other females.

The Lay of the Land

Many aspects of the female-female contest for copulation are understudied, and the same is true of FSC (Neff and Svensson 2013). Indeed, there is practically no direct evidence on this topic at all. Nonetheless, it is plausible that FSC could be common. And if so, it could well have been important in the evolution of animal behavior, cognition, and psychology, and maybe in particular in humans. Given the dearth of direct evidence, the approach taken here is to first provide an overview of the evolutionary requirements of FSC. This is followed by a brief review of the direct and indirect evidence in favor of each form of FSC: in relation to the partners of other males, and in defiance of dominant females. A discussion of the behavioral mechanisms that could facilitate the operation of FSC in nature is then provided, along with a discussion of the relevance of FSC to human evolution. A conclusion is then provided that looks to the future, at the questions that remain to be addressed.

Female Multiple Mating (FMM)

FSC requires that there are benefits to female multiple mating. In males, multiple mating is expected to arise due to the linear relation between the number of matings that a male secures and a male's total paternity. Just such a relationship was found in Bateman's classic study on the fruit fly, *Drosophila melanogaster* (Bateman 1948). In contrast, females have often been viewed as the limited sex, with fitness being determined by reproductive output rather than mating rate. Yet even in 1948, Bateman was able to find evidence that females increased their reproductive success with the addition of extra mates. Moreover, females have been observed to mate multiple times with multiple partners in multiple species across multiple taxa. Ascribing this all to male activity with the implication that the female is just a passive vehicle now seems absurd (Trivers 1972), and recent work has rightly rejected this simplistic dichotomy. Multiple mating is as much a female mating strategy arising from female

action as it is a male mating strategy based on male action.

But why do females mate multiple times? The act of copulation is associated with a number of costs (Jennions and Petrie 2000; Forstmeier et al. 2014). Copulation itself can be associated with direct damage to the female reproductive tract, for example, in species where the male penis carries spines, or it may simply use up a crucial resource – time. Likewise, precopulatory behavior can injure females. Postcopula, there are further risks resulting from the transmission of sexual diseases by multiple mating, while female longevity has been shown to decline due to the transfer of male-derived ejaculate products that raise a male's paternity at a cost to female survival. Mixed ejaculates are also associated with increased risk of embryo mortality via polyspermy. And there may be additional dangers if predation risk is increased in copula (or if a female suffers costs due to attacks by her partner or by other females). Given this, there must be clear benefits to FMM.

The most obvious direct benefits arise when the female herself benefits from mating, because the male provides a nuptial gift, such that more mating results in greater resource acquisition. Another example is the increased parental care that a female can obtain if she mates with more males, as a larger number of males will have a stake in her brood. Mating may also cause a reduction in male harassment or a decrease in the risk of male-driven infanticide. A final – special – example is that of fertility assurance. Females may become sperm limited in situations where some males have reduced fertility, where males invest few sperm per copulation (due to the partitioning of their resources across multiple females), or where there are limits to the length of time that sperm remain viable. All of these benefits provide reasons for females to mate multiple times: to accrue benefits to themselves in terms of resources or to ensure all of their eggs are fertilized (Jennions and Petrie 2000).

In addition to these direct benefits to the female, females can also obtain indirect genetic benefits to their offspring via multiple mating. A female can mate with a more ornamented male to obtain “attractiveness genes” (in so far as the

male ornament is preferred by other females) or “viability genes” (where ornament size correlates with male genetic quality). A female can thus trade up genetically by multiple mating if she mated first with a low attractiveness or low genetic quality male. In other cases “compatible genes” will be more important. Here, multiple mating can open up postcopulatory mechanisms that can select for compatibility (based on relatedness, MHC complexes, selfish element suppressors; Forstmeier et al. 2014). Alternately, multiple mating can be a simple bet-hedging strategy to increase the genetic diversity of a female’s offspring. In this case, multiple mating can either compensate for nonperfect female mate choice or increase the chances that some offspring fit their environment (Fox and Rauter 2003). As a final indirect genetic benefit, it is notable that, postcopula, “cryptic female choice” and “male sperm competition” are enabled by multiple mating and may simply select for sons that are good at fertilization – as such sons will inherit their father’s more competitive sperm.

Extra-Pair Copulation and FSC

As seen above, there are various benefits to multiple mating that are necessary for FSC. However, FSC also requires that multiple mating takes place in a social context. It is not possible to “sneak” in isolation. A simple social context is the monogamous pair bond. Here, a female is joined in a social pair with a male, and they jointly raise their offspring. However, the benefits of female multiple mating remain, even in this monogamous context. This can lead to selection for female alternate mating strategies, such as extra-pair copulation (EPC) or FSC (which is in this context a subclass of EPC).

EPC arises when a male or female mates with an individual other than their partner. It can be driven by males or females. Males can force females to mate with them in the face of true female resistance (forced copulation, coercion) or females may solicit males to mate with them (Griffith 2007; active female solicitation). Usually the interaction between the sexes reveals that

males search and display to females and that the females passively accept such advances, or put up a threshold of resistance (Westneat et al. 1990). The females’ behavior is presumably a reflection of the costs and benefits associated with extra-pair paternity. It is in this context that FSC subclasses of EPC might evolve.

A classic example of this FSC-EPC was provided by Kempenaers et al. (1992), who combined behavioral and genetic data to show that female-driven EPC was common in monogamous pairs of the blue tit, *Parus caeruleus*. In the wild population studied, 31 % of clutches included extra-pair paternity. Further, of the 7 EPCs (out of 90 copulations) observed, more than 70 % were classified as female driven. In these cases, females moved onto the territory of neighbors and were either chased off by the resident female or – if undetected – were sometimes able to solicit and take part in an EPC. The observation that resident females showed aggression toward intruders highlights the extra costs to this form of EPC, which must nonetheless be outweighed by the benefits, and provides evidence of a selective pressure that could promote the evolution of costly female sneak behaviors leading to copulation.

Primate Tactical Deception and FSC

Another class of species in which FSC-EPC could be important is the primates. Exclusive pair bonds are rare in most mammals (around 3 %). But they are relatively common in primates, with 14–18 % of species forming monogamous sexual bonds (Drea 2005), while the percentage is even higher if nonexclusive “pair” bonds nested within hierarchies are included (such as when a male has exclusive access to several females, see “[Hierarchies and Defiant FSC](#)” below). Female-driven EPC has been observed in several primate species, and male mate guarding behavior is known to be common (Drea 2005). Females are also known to take part in competitive interactions with other females, as well as to use various forms of physical and social punishments (Stockley and Campbell 2013). Hence, the FSC forms of EPC could be common in primates.

An advantage to recent studies on EPC in primates is that a number have started to provide insight into the psychological processes and cognitive mechanisms that underlie EPC. For instance, Overduin-de Vries et al. (2015) found evidence of EPC based on tactical deception in captive populations of the macaque species *Macaca mulatta* and *Macaca fascicularis*. They observed that females appear to deliberately create distance between themselves and other females before EPC events – a more complex level of cognitive processing than chance exploitation of a peripheral location but less complex than taking the perspective of other females into account (e.g., by deliberately hiding out of view behind screens). Similar tactical concealment was also observed in a wild Ethiopian population of the gelada monkeys, *Theropithecus gelada*, in a recent study by le Roux et al. (2013). As tactical deception is known to occur in relation to food and other nonsexual contexts in fish, corvids, apes, and monkeys (Overduin-de Vries et al. 2015), this behavior could also be widespread in FSC contexts of EPC. But at present there is little direct evidence for FSC-EPC in primates or of the role of tactical deception in this. This is due mostly to a lack of studies. Hence, such mechanisms *could* often be utilized in an FSC-EPC context, and there remains a need for further studies on this issue to determine if this is the case.

Hierarchies and Defiant FSC

Another social context in which FSC might appear is that based on the rank and social hierarchy seen in a variety of species, including cetaceans, elephants, corvids, and primates (Overduin-de Vries et al. 2015). A diverse array of such hierarchical systems exists. But the most relevant in terms of the evolution of human psychological processes are the primates. Here, hierarchies are based on both male and female rank (Drea 2005). Higher-ranked females often have higher reproductive success. And such females are also known to suppress the reproduction of lower-ranked females (Drea 2005). Hence, another type of FSC that could be important is

that of “defiant FSC” – where a lower-ranked female mates with a male, in defiance of a higher-ranked female. As in the case of tactical deception, there is little direct evidence about defiant FSC. Nonetheless, a number of studies have provided indirect evidence that this could be common. For instance, both Overduin-de Vries et al. (2015) in macaques and le Roux et al. (2013) in gelada monkeys found evidence of male rank-related audience effects on EPC – females and lower-rank males were less likely to copulate when a male of higher rank was nearby and were often punished by these males if sighted. Female rank-related audience effects were not observed in either case. However, these are the first studies of their kind and highlight the potential for such defiant FSC to arise in nature.

FSC in Humans: “Woman Beware Woman”

It has also been suggested that FSC is likely to be common and important in humans. Like other primates, humans have complex social structures and form close pair bonds. Females (women) have flatter “hierarchies” than males (men) (Sidanius et al. 1994) but are known to enforce these via subtle social as well as physical means (Campbell 2013; Stockley and Campbell 2013). Women are also known to “cheat” on men and to punish this behavior in other women, especially if the target of the FSC-EPC was “their” man. In street “gangs” such punishment can even lead to the death of another woman (Campbell 2013). Hence FSC is likely to be important in humans and could well involve – or have been involved in the evolution of – the complex psychological processes and cognitive systems that define humans. But once again there is very little solid observational or experimental work that would establish human FSC beyond anecdotal reports; so more studies are needed.

Conclusion

Female sneak copulation (FSC) is likely to be common in nature. However, all female-female

sexual competitive interactions remain relatively poorly investigated, and FSC is no exception. Nevertheless, the field is starting to move forward, and it is likely that within the next 5–10 years the mechanisms of FSC, its prevalence in nature, and its importance in human evolutionary psychology will be better known. The results are awaited with anticipation!

Definition

Relationships between two or more females that are based on mutual benefit.

Introduction

When females have abundant resources, they birth more offspring and have more offspring survival than females who have limited resources (Mulder [1987](#)). Allies who share a common goal are likely to share resources, so individuals who form alliances have a greater likelihood of survival and reproduction than individuals who do not form alliances (Chapais [1995](#)). Female-female alliances are often formed for food competition,

particularly among nonhuman primates, but alliances afford females a variety of advantages including physical protection, emotional support, and child care.

Benefits of Female-Female Alliances

Alliances increase reproductive fitness, or one’s ability to pass genes to subsequent generations, by enhancing one’s ability to secure and maintain resources. Food and status are common resources obtained through alliances (Chapais [1995](#)). Another valuable resource, particularly among human mothers, is child care (Hrdy [2009](#)). Human infants are born altricial – they require extensive care for survival. Allomothers, or caregivers other than the mother or genetic father, are highly valuable to a mother. If a mother does not have kin nearby, a female-female alliance that results in child care increases her children’s likelihood of survival.

Female-female alliances are also associated with mental health advantages. Women’s friendships are characterized by high levels of social support and self-disclosure, which are thought to positively impact mental health (Uchino et al. [1999](#)). The more female friends co-ruminate, or discuss negative feeling and experiences, the closer they feel to their friend (Rose [2002](#)). Another benefit of female-female alliances is support during competition with rivals. Women’s intrasexual competition typically occurs by indirect actions such as gossip and rumor spreading aimed to promote equality (Campbell [1992](#)).

Costs of Female-Female Alliances

Although some aspects of women’s same-sex friendships promote mental health, other aspects may negatively impact health. Co-rumination among girls and adolescents predicts increased anxiety and depression over time (Rose [2002](#)), and co-rumination among women is associated with increased levels of physiological stress (Byrd-Craven et al. [2011](#)).

Women's same-sex friendships are also fragile relative to men's same-sex friendships (Benenson and Christakos 2003). Competition for resources, such as attention from a mate or status, can dissolve an alliance. If women portray themselves as superior to their allies, exclusion from the group is a likely consequence (Campbell 1992).

With Whom Do Females Form Alliances

Genetic relatedness, similar social status, and similar age are variables that increase the likelihood that females will form an alliance (Chapais 1995). Indeed, maternal kinship bonds are one of the primary sources of social status and alliance formation among many nonhuman primates. Alliances form among females who share similar goals such as guarding food and mates (Rucas, Gurven, Winking, and Kaplan, 2012). Familiarity is also a factor in alliance formations. Females are more likely to be allies the more often they interact socially (Dunbar 1980).

High-status females tend to form alliances with other high-status females, and befriending a high-status female can increase one's own social status (Chapais 1995). Females sometimes betray kin and close friends if a prospective ally can help them improve or maintain their own rank (Benenson 2013). Moving up the social rank by forming an alliance with a high-status female is rare because there is little advantage to a high-status female to forming an alliance with a low-status female. Although alliances typically form between individuals of similar social status, there are exceptions. In bridging alliances, one ally is ranked below a target, and the other ally is ranked above the target (Chapais 1995). The alliance results in the lower ranked ally moving up in rank above the target. In a revolutionary alliance, both allies initially rank below the target but both move up in rank above the target after the alliance.

Conclusion

Female-female alliances are relationships between two or more females that are based on

mutual benefit. Alliances enhance an individual's ability to secure and maintain resources, which ultimately increase one's reproductive fitness. Some of the resources that females secure through alliances are food, territory, status, mates, and child care. Female same-sex friendships can provide social support, but they can also increase physiological stress. Alliances between women are based on equality, and they are quick to dissolve if an individual is perceived as acting superior to the group.

Intrasexual competition; Rivalry; Women

Definition

Competition that females of a given species engage in against each other in order to access limited resources, including mates, that impact on their survival and reproductive success.

Introduction

Females of many species compete with each other to gain access to limited resources that directly impinge upon their survival and reproductive success. Competition is usually highest among members of the same sex, given they most often compete for the same resources, including mates (see Stockley and Campbell 2013, for a review). Within-sex (i.e., intrasexual competition) is therefore a significant evolutionary pressure. During the last decade or so, there has been noteworthy research that indicates females can be as aggressive, or even more so, in competitive interactions than males (see Stockley and Campbell 2013, for a review).

Originally, much of the literature pertained to male intrasexual competition, but the focus has turned within recent decades to females (see, for example, Stockley and Campbell 2013; Fisher 2017). Perhaps this former neglect is because female competition is typically characterized as being subtle and covert (Hrdy 1999). It rarely involves escalating contests or exaggerated secondary sexual characteristics (Clutton-Brock and Huchard 2013), and in humans, women suppress it when men are present in order to avoid seeming undesirable (Cashdan 1999).

Female Aggression

Researchers have proposed a link between aggression and competition, such that aggression is necessary for competition to occur (e.g., Schuster 1983). While men are often found to engage more frequently in direct physical aggression than women, the latter engage more frequently in indirect aggression. Indirect aggression occurs when a perpetrator attempts to cause harm but simultaneously tries to make it appear as though there is no harmful intention (Björkqvist et al. 1992). Girls and women use indirect aggression when they engage in behaviors such as breaking confidences, criticizing others' appearances, excluding others from the group, or spreading gossip (Björkqvist 1994; Owens et al. 2000). Social networks are often used, which further obscures intentions to cause harm and thereby reduces the possibility of retaliation and counter-aggression (Björkqvist et al. 1992).

Campbell (1999; but see Liesen 2013) suggests that women's lack of direct physical aggression is a successful female adaptation that results in reproductive benefit. She argues that when women become mothers, they become the primary caregivers and protectors of their children. Hence, it is important for mothers to remain alive, leading to the use of indirect, low-risk, strategies to resolve disputes. She posits girls and women avoid competing for status and instead focus on competition for resources, using indirect means (see Liesen 2013 for a review). There are alternative views; for example, Liesen (2013) proposes

girls and women use direct and indirect strategies, pursuing dominance and status to gain access to material resources (e.g., food, space, mates) but also to reduce female harassment and establish alliances. She argues that for girls and women, the goal is not to be at the top of a hierarchy but rather the center of attention where the maximal social, material, and reproductive benefits are located.

Competition for Mates

Women compete in many arenas, just like females of many species. Females compete for access to desired mates (see Fisher 2013 for a review), as well as for resources that may influence their reproductive fitness outcomes, such as food, nest-sites, protection, territories, and by interfering with the reproduction of other females (Stockley and Bro-Jørgensen 2011).

Women are obligated to significantly invest in their children, at least in terms of gestation and lactation, which leads to a decreased reproductive potential relative to men who have a far smaller obligatory investment. Females of many species compete when there are high levels of maternal investment, when paternal investment is beneficial, and where there are large aggregates of individuals living together which increases competition for proximal resources (Apicella and Dreber 2015). Humans show all of these features. In addition to maternal investment, men, compared with males of other species, tend to provide high levels of paternal care for children (Clutton-Brock 1991). Humans also live in social groups with plentiful opportunities to be in close proximity to other mothers with children, leading to competition for scarce resources that effect the survival of themselves and their children, as well as further reproduction.

It is undeniable that women compete for mates. Universally, women intrasexually compete to gain access to high quality mates who possess phenotypic characteristics that indicate high genetic quality, an interest in (and ability to provide) paternal care (Gray and Anderson 2015), and an ability to accrue resources (see Fisher 2013 for a

review). Women use a variety of information sources to make decisions about how and when to effectively compete. For example, women rely on information about rivals in their local environment to determine their own and potential rivals' mate value, alongside the value of potential mates (Fisher and Fernández 2017). As another example, factors such as a scarcity of quality mates leads to increased intensity in competition (Dillon et al. 2017). The bulk of research findings apply only to single, young women from Western cultures and has, for example, neglected women who are married, above the age of the average college student, or mothers (Fisher 2017). Further, the vast majority of past work has focused on the hormonal underpinnings of women's mating competition, or women's use of beautification or physical alterations to outcompete mating rivals.

Competition Between Mothers

The overwhelming neglect of competition among mothers is particularly curious, given that such competition has direct outcomes on individual fitness. Mothers have found and potentially secured a mate, but they still need to ensure that mate provides care, time, and resources to herself and any resulting children. Also, once a woman becomes a mother, she does not necessarily stop reproducing, and indeed, she may engage in behaviors to remove the current child to increase her chances of reproduction or in securing a better mate (Hrdy 1999). Consequently, locating, obtaining access to, and retaining a quality mate are highly critical to a women's reproductive success, in that it will lead to healthy children who ideally will survive and reproduce.

However, there are other domains outside of mating that impact on a mother and her child(ren), such as relational status, social dominance, and obtaining sufficient resources (Fisher and Moule 2013). These necessary resources improve child longevity and include clean drinking water and medicines, given that the most common cause of mortality for children under 5 years of age is infectious disease (68%; Black et al. 2010). Women, like all mammals, invest substantially,

from the gamete stage, throughout pregnancy, lactation, and childcare. To benefit from this investment, they must ensure their children survive, which dictates that they compete for limited resources in support of themselves and their children (Stockley and Bro-Jørgensen 2011). The importance of this competition must be emphasized; Clutton-Brock (2009) suggests that females in many species may compete more intensely for reproductive resources than access to mating opportunities.

Cooperation and Competition

One of the most important issues for understanding female intrasexual competition is the delicate balance between cooperation and competition with same-sex others. The most likely allies are those who are around the same age, with similar personality characteristics, values, and mate value (see Fisher and Fernández 2017, for a review). However, these are also the most probable rivals for mates, status, or access to resources in support of children. The quandary of competing with potential allies poses a problem. Women may gain particular benefits through intrasexual competition (e.g., status, power, dominance, resources, potential mates), but at the cost of their friendships or alliances with other women. Maintaining a cooperative relationship is critical; women engage in intense cooperation because male partners can be absent, noncommittal, unable to help, or abusive. Without the assistance of other women, women and their children are in serious danger (see Sokol-Chang et al. 2017 for a review). In fact, circles of supportive women are at times called “survival networks” (Dominguez and Watkins 2003; Högnas 2010). Therefore, the issue becomes: how do women compete against same-sex friends yet remain in strong sharing, dyadic relationships with these individuals? One solution is to use indirect aggression, as outlined. Women may attack their victim circuitously, prohibiting the likelihood of being correctly identified (Björkqvist 1994). Alternatively, one may use an indirectly aggressive act under the ruse of self-improvement. A strategy women (and men) rely

on is self-promotion, whereby one attempts to make herself look better than a rival. However, it is possible that she could say that she was not involved in a competition but merely engaging in self improvement, thus hiding any intention to compete (which may explain why self-promotion is the most often used strategy for intrasexual competition for access to, and retention of, mates; Fisher et al. 2009). In this way, competitiveness is hidden and enables women to remain allies with those they are competing directly against. As women proceed through their lifespan and change (e.g., have children, experience increases or decreases in their mate value and reproductive potential), they encounter situations where they must make new decisions about whether to cooperate or compete (see Fisher et al. 2017). Each of these situations has limitations and exceptions, as women may cooperate as a strategy to obtain mates, and mothers may forgo cooperation in favor of competing for limited resources for themselves and their children, for example. Herein lies the interesting dichotomy in women’s relationships with other women, as they must decide between providing cooperative support or being competitors with the goal of maximizing their own reproductive success.

Conclusion

Female intrasexual competition is observed in many species. The outcome of intrasexual competition influences access to limited resources that directly affect one’s survival and reproductive success. Consequently, female intrasexual competition is a significant evolutionary pressure. Here we specifically review women, and the link between their use of aggression and competitive behaviors. Women intrasexually compete to gain access to quality mates and also for resources, status, and other considerations that impinge upon themselves and their children. Women are faced with a difficult decision of whether to cooperate or compete with same-sex others; given the benefits resulting from cooperation, competition is likely to occur in a way that disguises either the perpetrator or the actual competitive act itself.

Reproductive competition; Women's intrasexual competition

Definition

Behaviors or actions that females engage in against same-sex others for the purposes of maximizing reproductive fitness.

Introduction

Female intrasexual competition has gained considerable momentum as a topic of study (see Fisher 2013). The majority of this work, as it applies to humans, is focused on mating competition. However, there has been a surge of recent interest in human competition outside of this context. Thus, competition over limited resources important for reproductive fitness is first reviewed and then issues pertaining to mating competition. Given the strategies involved in women's intrasexual competition are typically subtle and indirect, research on relational and indirect aggression is presented. After this discussion, the four types of strategies that women use within mating competition are reviewed, followed by a section on future work.

Human females, like females of many mammalian species, are group living and reap the benefits associated with sociality. Among

mammals, these benefits may include decreased predation and increased access to resources. However, individuals within groups also face costs, such as the transfer of pathogens, increased probability of infanticide, and competition for limited resources and mates (for a review of the costs and benefits of mammalian sociality, see Ebensperger et al. 2012). The outcome of competition for resources and mates is critical, as it confers reproductive benefits that directly influence reproductive success.

Competition for Limited Resources and Mates

These limited resources are ones that vary in quality and may include food, territories, and protection (see Stockley and Bro-Jørgensen 2011), all of which impact on the well-being of the female and her offspring. Gestation, and in particular, lactation, places high energetic demands on females, such that the ability to locate and acquire food may constrain reproduction. Indeed, the distribution of food is thought to be one of the major determinants of within group competition (Isbell 1991). For example, due to limited food resources, there may be clearly defined female dominance hierarchies resulting from aggression, increased home range size in conjunction with increased group size in order to acquire additional resources, and longer distances traveled each day in response to increased group size (Isbell 1991).

Therefore, females should compete for access to food, in order to sustain reproduction. This competition has many repercussions. For example, Stockley and Bro-Jørgensen (2011) review how dominance is important for some species, given that dominant females may have improved access to better food, drinking sites, nest sites, territories, and better protection (e.g., be in the central, safer position of a pack during an attack). However, while dominant females seem to have higher reproductive success in many mammalian species, especially in free-ranging species where resources are limited, it is not ubiquitous (see Stockley and Bro-Jørgensen 2011).

As a side note, that females intrasexually compete outside of a mating context has led some scholars to question Darwin's view of sexual selection and argue that it is overly narrow (e.g., Clutton-Brock 2009). Thus, there has been debate as to whether there should be a distinction for within-species dynamics to be divided between sexual selection (i.e., competition for access to, or retention of, mates) and social selection (i.e., access to, and retention of, resources that impinge upon reproductive success but are outside of a mating context).

With respect to competition for mates, it must first be noted that females and males of many species energetically invest to differing degrees in offspring (for a review, see Trivers 1972). In mammals females substantially invest energetically in offspring, so they must compete to guarantee the highest rate of return on this investment (i.e., that their offspring survive and reproduce). Males, by contrast, do not need to invest much, and indeed, in approximately 95 % of mammalian species, there is a pattern of intense male intrasexual competition for access to mates and minimal parental investment, coupled with discriminative female choice (Clutton-Brock 1989).

However, in humans, many men do provide some investment, by provisioning, childcare, and/or protection, and hence, women intrasexually compete for men high in these attributes. Men differ in their abilities to protect offspring and in their abilities to provide resources. Protection and provisioning by men very often increase the survival rate of offspring, and as a result, are important resources for women. Subsequently, good protectors and providers are in greatest demand and are relatively rare. Moreover, men with superior phenotypes (which may indicate superior genotypes) are also in demand. Women attend to cues that may signal sterility or impotence (Campbell 1995) and hence, notice physical indicators of youth, strength, and libido when selecting mates. Note that some of women's mate preferences for men's physical characteristics such as facial masculinity may vary according to their ovulatory cycle status, but this has recently been debated (see Marcinkowska et al. 2016).

Inherent in Darwin's (1871) theory of sexual selection is the idea that characteristics evolve to enable individuals to gain advantage over same-sex competitors thereby securing successful matings. Moreover, both elements have evolved in unison, so traits that are most preferred by the opposite sex are the traits that are of most benefit in same-sex competition. While there are some similarities, the sexes differ in their mate preferences in conjunction with the constraints of reproductive success (e.g., Buss 1989; Trivers 1972). That is, although both sexes consistently show a desire for mates who are kind, intelligent, and loving, there are some notable sex differences. Universally, men typically express a strong preference for attractive women as potential mates (e.g., Buss 1989), and thus, women compete in terms of attractiveness. Likewise, women tend to have a strong preference for men with financial security and access to resources (e.g., Buss 1989), so men compete to appear wealthy. Indeed, women compete via their attractiveness, whether it be through self-promotion of their own appearance, or derogating rivals' appearance (Fisher and Cox 2011). Men compete via displays of their wealth (e.g., self-promoting or derogating the resources of other men; Fisher and Cox 2011).

Last, the anticipated duration of the relationship influences mate preferences. For example, women seeking short-term relationships place a higher premium on appearance (i.e., potential phenotypic cues of gene quality) and decreased importance of personality traits or traits related to accruing resources. Men seeking short-term relationships generally seek ease of sexual access and decrease preferences overall, but emphasize physical attractiveness and youth (i.e., potential proxies for fecundity) in long-term mates (see Schmitt 2014). Thus, individuals should adjust the form of intrasexual competition in relation to the intended duration of the relationship, given there are shifts in mate preferences. Findings indicate partial support, as reviewed later (Schmitt and Buss 1996).

Unlike competition for resources, there has been considerable research into competition for mates. Therefore, the remainder of this entry will focus on the latter topic.

Types of Aggression Used by Women in Competition

The primary way that women compete with each other is through the use of relational and indirect aggression. The sexes do not differ significantly with respect to the frequency of aggressive behavior in general (e.g., Bettencourt and Miller 1996). However, the form of the aggression is sexually differentiated, as women are thought to engage in more relational and indirect aggression than men. If the aggression involves the manipulation of peers via their relations and reputation, and/or interference with friendships and group inclusion, it is relational aggression; the only criterion is that relationships are the central consideration. Another form of aggression is indirect aggression, where a perpetrator tries to inflict harm while simultaneously attempting to make it appear as though there was no harmful intention (Björkqvist 1994), presumably to decrease the likelihood of retaliation. Often indirect aggression is used within the context of relationships and social networks, directed at someone's reputation, or for the purposes of group exclusion, for example, and hence, it often falls within the realm of relational aggression.

Benenson et al. (2013) argue that one form of relational aggression, social exclusion, is of particular importance to girls and women. Social exclusion may reduce the number of competitors for resources that relate to reproductive fitness, and thus, be an effective strategy to aggress against other women. They further posit that women's friendships may be less instrumental than men's friendships, and thus, the cost of ostracism to the perpetrator is low. Indeed, compared to men, it does appear to be an effective and often used strategy among women, as they face relational aggression via ostracism more often, are typically more affected by it, and react more strongly (Benenson et al. 2013). One reason for its effectiveness and frequency of use may be that women tend to prefer interactions that are one-on-one, whereas men tend to engage in larger groups; the probability of social ostracism is greater in the former than in the latter (see Benenson et al. 2013 for a review).

Indirect aggression is more often used by women than by men, and women less frequently engage in direct physical confrontation (e.g., Campbell 1999). However, it should be noted that women sometimes do engage in direct aggression; for example, Burbank (1987) found 61 % of the 137 cultures she studied documented women's physical aggression, typically in the form of women fighting other women over men in an effort to protect their relationships and resources for their children. Moreover, Campbell (2004) found that women's physical aggression most often occurs among lower socioeconomic classes, which may indicate that competition increases when resources are more limited. However, even in contexts where variables that influence the severity of competition are observed, such as sex ratios that are biased against women, age of oneself and potential rivals, or high variance in men's resources, women's use of direct aggression is still less, as compared to men (Campbell 2013).

There are various proposals as to why women rely on indirect aggression. First, because women generally possess less physical strength than men, they evolved alternative methods to aggress, and consequently, rely on different competitive strategies (Björkqvist 1994). Second, Campbell (1999) contends women are typically the primary caregivers and protectors of their children and engage in indirect, low-risk strategies to resolve disputes, which helps ensure they (and their children) remain alive. Third, Hess (*in press*) points out that the high costs of direct aggression are the same for all female mammals, yet nonhuman mammals routinely engage in physical aggression. Therefore, she argues that women engage in indirect aggression because it is particularly effective for competing against women, not because it is safer to the perpetrator.

How Women Compete for Mates

There appears to be four primary behavioral strategies that capture women's intrasexual competition for mates. The first is self-promotion, which is the enhancement of one's positive qualities,

relative to those possessed by members of the same sex. This strategy was first documented by Buss (1988), who surveyed people's use of self-promotion for the purpose of mate attraction. He found that among other characteristics, women self-promoted by manipulating their appearance and men by displaying and bragging about their resources. Walters and Crawford (1994) extended Buss' work, widening the focus to be an investigation of self-promotion for the purpose of intrasexual competition rather than solely mate attraction. They largely replicated his results.

The second strategy that has been well explored is competitor derogation. This strategy refers to any act used to decrease a rivals' mate value relative to oneself. Using surveys, Buss and Dedden (1990) found that women self-report a tendency to derogate rivals' appearance, while men self-report they derogate rivals' physical abilities and resources.

Researchers have examined self-promotion and competitor derogation together, in order to determine their use according to sex, relationship status, and context. For example, in a study by Schmitt and Buss (1996), both sexes were found to self-promote and derogate potential competitors when pursuing a relationship, but that the length of the expected relationship influenced strategy use. With respect to self-promotion, men expecting a short-term relationship said they would emphasize immediately available resources, whereas those seeking a longer-term relationship focused on future resource potential. Women in the short-term scenario reported they would emphasize their sexuality and attractiveness, whereas those pursuing a long-term relationship promoted their faithfulness and sexual restrictiveness. The pattern for competitor derogation was somewhat similar, in that women pursuing a short-term relationship would describe potential rivals as "ugly," "frigid," and "unhygienic," and emphasize a rival's promiscuity in the long-term condition. Regardless of duration, men reported that they would say potential rivals were "promiscuous," "dangerous," and "unhygienic."

In a meta-analysis, Schmitt (2002) found women were far more effective at using physical

appearance for the purposes of self-promotion than men, but that this sex difference was dramatically reduced when it was within the context of competitor derogation. Generally, both sexes were perceived to be less effective when using physical appearance-related tactics for competitor derogation, as compared to self-promotion. In contrast, when using tactics related to resources, the sex difference was large, such that it was judged more effective when used by men than by women for self-promotion, and this difference increased when used for competitor derogation.

To make a more direction comparison of the two strategies, Fisher et al. (2009) asked students in a forced choice survey whether they would be more likely to self-promote or competitor derogate for particular contexts (e.g., regarding physical appearance). They showed that self-promotion was selected significantly more often, regardless of context, sex, or relationship status, than competitor derogation. They then asked members of the community to complete continuous measures and found that women, more than men, reported using self-promotion, while men reported more use of competitor derogation than women. Romantic relationship status mattered; dating and single individuals used both strategies more than those in common-law or married relationships.

Aside from the strategies of self-promotion and competitor derogation, there is also mate manipulation and competitor manipulation. Fisher and Cox (2011) asked students to list the ways in which they compete for mating attention, which replicated the existence of the former two strategies, and lead to the discovery of the latter two strategies. Mate manipulation is when an individual removes the target of the competition so that no competition is necessary, such as by sequestering the mate or displacing attention from a potential rival. The other is competitor manipulation, wherein an individual tries to convince a rival that the potential mate is not worth the costs of competition. They also found that most tactics were classified as self-promotion, followed by mate manipulation, competitor derogation, and competitor manipulation. There were significant sex differences as well; women were more likely to

report self-promoting their physical appearance, and men were more likely to list direct actions such as bullying or derogating a rival's material possessions.

The discovery of mate manipulation as a strategy was particularly interesting, as it highlights that intrasexual competition does not end at mate acquisition. After an individual has selected a suitable mate and gained access, she must still engage in competition to retain him and prevent him from leaving the relationship. The use of the four strategies may thus change, depending on one's romantic relationship status, but also according to the intended duration of the relationship, one's level of commitment towards it, perceived mate value of oneself and mate, and the existence of potential rivals who may infiltrate the relationship. These potential influences need to be explored by future researchers.

Issues to Address in Future Work

One area that warrants further investigation is how to include a multigenerational approach into studies of female competition. As Stockley and Bro-Jørgensen (2011) indicate, females use strategies that influence the quantity of offspring but also the quality of offspring in terms of survival and reproductive success. Thus, the key is not looking at the immediate offspring, but rather to take a long time perspective and document the outcomes in a multigenerational view.

Further, as mentioned, there has been significant research into women's intrasexual competition for mates, but less work into resource competition. One avenue to gain insights into what resources are at the heart of women's competition may be to look at cooperative versus competitive mothering and see how women strategize to maximize their reproductive fitness overall, even if it means sacrificing equal shares in gained benefit. For example, one inroad may be to join the ongoing debate involving cooperation for childcare and allomothering. Communal breeding is generally understood to result from competition over resources relevant to reproduction (Mace 2013). Among humans, for example,

there may be competition for limited household resources, whereby inclusive fitness may be improved by sharing goods (even if the portions are unequal) rather than potentially harming relatives. While some scholars focus on cooperation among allomothers who provide childcare for related or unrelated individuals (e.g., Hrdy 2009), others focus on how this model is not readily applied to all human populations. For example, Strassmann (2011) reports that among the Dogon of Mali, mothers are critical for child's survival and cannot be replaced by any other individual. She argues that cooperative breeding is a facultative response to a given environment, and as such, it is not species typical. The extent to which cooperative breeding is an appropriate model for humans thus remains to be determined. However, some researchers suggest that cooperation and competition go hand-in-hand and that it is reproductive competition between and within families that has led to fertility patterns such as menopause, and cultural norms such as marriage patterns, inheritance of goods, and location of residence (Mace 2013).

Research into cooperation and competition also illuminates a second issue: what causes a woman to decide that a potential member of the group represents an ally versus a rival? The literature on indirect aggression suggests prosociality may be the key. Aggressive individuals may be able to remain central to the group, obtaining personal gains with minimal personal cost. While group living leads to inevitable costs and competition among group members, it also leads to the acquisition of resources that may not be achievable by individuals working alone (Hawley 2003). Thus, Hawley (2003) proposes that in order to effectively compete, some individuals within the group are prosocial (i.e., indirect and cooperative), while others are coercive (i.e., direct and assertive). To maximize advantages, one should be high on both the dimensions of prosociality and coercion. These bi-strategic individuals possess high social competence, as they may act in a highly aggressive manner and still retain their status in a peer group. Within the context of competition for resources necessary for survival of oneself and one's children, being

able to sustain power and yet maintain social alliances would be highly advantageous.

- [Women's Mate Value](#)
- [Women's Long-Term Strategies](#)

Conclusion

Women deploy a variety of strategies when engaging in intrasexual competition, with the theme that they tend to favor indirect and relational aggression. Human strategies for mating competition, such as self-promotion, competitor derogation, mate manipulation, and competitor manipulation show the nuances of directing one's actions and behaviors towards different audiences to reap the best competitive advantage. The overwhelming majority of literature pertains to women's competition for mates, yet there has been recent interest in competition outside of this realm. Indeed, given that women heavily invest in children, one might argue that they should compete more for access to resources that improve their children's survival than for mates, but this possibility needs to be explored. In general, the research on competition for resources shines light onto areas that need to be further investigated, including the actual resources that women compete over that enhance their reproductive fitness, and the strategies they use.

Females Remain with Natal Group

Alex K. Piel

Definition

In most mammalian (social) species, one or both sexes disperse, either to avoid inbreeding or as a result of increased competition for limited resources. The sex that remains in their natal group is considered **philopatric**, remaining and breeding in their natal range or group (Clutton-Brock and Lukas 2012). The sex that migrates or disperses to another group to find mating partners exhibits **natal dispersal** – a permanent movement the animal makes from its point of origin to the place where it reproduces or would have reproduced if it survives (Greenwood 1980). If there is migration subsequent to reproduction,

we call this **breeding dispersal** – movement of individuals that have reproduced, between successive breeding sites. Due to the costs of dispersing (see below), typically, individuals only disperse a single time in their lifetime. However, if an animal disperses more than once, they are considered **secondary dispersers** – permanent or semipermanent movement of breeding adults that have already left their natal group or range (Clutton-Brock and Lukas 2012).

Introduction

In any social species, one or both sexes typically disperse, while the other remains in their natal group. There has been contentious debate over the causes of dispersal, but primarily animals disperse either to reduce mate and food competition or else to avoid inbreeding. There are numerous benefits to being the philopatric sex or the sex that remains in their own natal group. These center around building and maintaining a detailed spatiotemporal map of food and water resources, threats (predators), and escape routes. Additionally, there are social advantages, namely, gaining support from kin, especially helpful when ascending dominance hierarchies within the group and fending off attacks from rivals (Clutton-Brock and Lukas 2012).

The Costs of Dispersal and Benefits of Philopatry

It is generally accepted that the sex that is most dependent on resources for reproduction (usually females among the mammals) should be philopatric, while the other sex disperses. For example, natal philopatry – at times accompanied by resource sharing from parent to offspring – predicts a kin-structured population and has been argued to represent a precursor for the evolution of sociality. Most social mammals, primates particularly, are characterized by this female philopatry, although examples abound of female transfer (Clutton-Brock 1989; Moore 1984). Some have argued that the direction of

sex-biased philopatry is a direct result of the mating system of the species in question (reviewed in Greenwood 1980).

In primates, scientists have historically attempted to decouple philopatry from bondedness (van Schaik 1983) and describe philopatry as an evolved, social response to within and between group competition dynamics, as well as infanticidal avoidance (Sterck et al. 1997). The decision to disperse, however, may be a far more active process. Williams and Rabenold (2005) suggested that in some male corvids, forays into neighboring territories were actually reconnaissance missions to evaluate potential mating opportunities for later dispersal. Accordingly, dispersing carries with it risks, especially for social animals. Resident individuals are often resistant to immigrants or even xenophobic, aggressing at new arrivees; immigrants must also compete with other dispersers, resulting in secondary and even tertiary dispersal attempts (Cheney and Seyfarth 1983). In some species where females disperse (e.g., African lions, meerkats, howler monkeys, prairie dogs), unless immigrating females usurp resident females, dispersers are faced with either founding their own social groups or dying.

Conclusion

In Jim Moore's (1984) 57-page manifesto on the topic of female transfer, he contextualized the historical significance of our attempts to understand animal (specifically, primate) sociality, beginning with Hamilton's (1964) work on inclusive fitness and continuing into the early work into matrilineal relatedness in macaques (*Macaca* sp.) and baboons (*Papio* sp.). The prevailing view, as Moore noted, was one of stable mammalian groups based on female kin, with exceptions noted throughout the Class (see above). He concluded by saying that "...while kin selection may be a very powerful force among close relatives... for many species it may be relatively weak or even negligible between more distant ones," and thus the numerous "exceptions" to female philopatry may actually support an earlier description of

primate groups as “loosely bound aggregations of individuals which may have little long-term core of kin” (Jolly et al. 1982). That interpretation notwithstanding, we can say that in the vast majority of social mammalian species, and primates specifically, females remain within their natal group, using strong kinship relationships to learn about and exploit their physical and social environment.

“Advocacy of women’s rights on the grounds of the equality of the sexes” (*English Oxford Living Dictionaries*).

Introduction

Feminism's history is both a compilation of women's experiences and a record of the different strategic interventions employed to argue women's cause (Joan Wallach Scott, *The Fantasy of Feminist History*).

Arguably one of the most maligned and misunderstood of terms, "feminism" has a long, complex, and dynamic history. Prejudices and politics aside, far from being a monolithic ideology, feminism is more aptly characterized as "feminisms" owing to the various theoretical approaches associated with it, such as liberal feminism, Marxist feminism, socialist feminism, radical feminism, intersectional feminism, transfeminism, anarchist feminism, and transnational feminism. Depending on both its national and cultural context, feminism may also stress different aspects of, and remedies to women's social and political oppression. Whereas Western feminism might focus more on individual rights, such as equal pay and opportunities for employment advancement, Eastern European or Latin American feminism might emphasize collective concerns such as labor rights. However, all feminisms necessarily subscribe to the denotative meaning identified in the Oxford English Living Dictionary (cited above) and are committed to women's advancement. How sex inequality is manifested and how best to address it has been a matter of debate, hence the term feminisms. "Central to feminism is the view that women's" secondary status in patriarchal societies "is socially constructed, and therefore open to change" (Hannam 2007). On the basis of this shared fundamental meaning, the singular "feminism" may be accurately used. Moreover, as feminist scholar Lorna Finlayson argues, feminism is best understood as a combination of "theory" and "praxis" (2016); that is, the activism associated with the various theoretical approaches.

Women's Oppression

Just as feminism is dynamic and responsive to cultural conditions, the longstanding patriarchal

system that it challenges is neither static nor universal. Historian Estelle B. Freedman explains: "Prehistoric artifacts suggest that men and women have at times shared spiritual prestige" (2002), which is a key source and justification for a dominant governing system, and prehistory offers ample examples "in ancient Egypt and among Bedouins in pre-Islamic Arabia" of powerful female leaders (Freedman 2002). Given evidence of more egalitarian societies in pre-history, historians such as Gerda Lerner and Karl Marx have speculated about patriarchy's origins (Freedman 2002). Some feminists have theorized "the subordination of women and found their explanation for it in the male 'need' to dominate the female" (Scott 1999), while Estelle Freedman explains how "a shift from subsistence agriculture to trade fostered . . . more highly stratified societies" (2002). Colonialism in Asia and the Americas also exacerbated unequal gender relations in the developing world: "Colonialism transported many ideas about gender that both reinforced existing inequalities and introduced new ones" (Freedman 2002). Whatever its origin, or origins, the institutionalization of the gendered hierarchy privileging men over women gave rise to feminism, and it coincided with the shift to a land-based economy driven by trade and private property ownership, wherein the female was regarded as the property of her father or husband. Traditional values and social expectations around women's childbearing and mothering have also played a major role in women's oppression. Moreover, against the backdrop of both nationality and ethnicity, it is difficult to disentangle the interlocking systems of capitalism and patriarchy, since the one fuels and reinforces the other.

Origin of "Feminism"

The term feminism, which originated with the French word "feminisme," entered the English language in the late nineteenth century (*New World Encyclopedia*). Both the term and the political movement associated with it arose in western society in the eighteenth century as a response to patriarchy's reliance on the political and social oppression of women as a class. Challenges to the status quo and women's oppression, however,

date back at least to the middle ages in France, with Cristina de Pisan's bold call for women's separate education in *The Book of the City for Ladies*, circa 1405. "Arguably the first woman in Europe to earn a living as an author" according to the World Digital Library, de Pisan "is widely regarded as an early feminist who spoke out for the rights of women and espoused female achievement". Inklings of "feminism" of a sort may also be found in the life and writings of the Greek poet Sappho, the German ascetic and composer Hildegard of Bingen, and the English anchoress Julian of Norwich from the early medieval period. In England, the seeds of modern feminism date back to the late sixteenth century (Finlayson 2016). British pamphleteer Jane Anger, whose name is a possible pseudonym, mounted an angry and vigorous challenge to the artificial constraints by which women were denied access to education, prevented from developing their intellect, and then unfairly condemned for their ignorance (Finlayson 2016). Similarly, in *Essay to Revive the Ancient Education of Gentlewomen in Religion, Manners, Arts and Tongues*, Royal governess Bathsua Makin "insisted . . . on the importance of women receiving an education" (Walters 2005). A rash of feminist proposals and polemics followed in America as well as Great Britain. In her seminal feminist work, *A Vindication of the Rights of Women: with Strictures on Political and Moral Subjects* (1792), Mary Wollstonecraft advances the views of de Pisan, Anger, Makin, and others, with her rigorous philosophical analysis of the conditions and deleterious effects of women's secondary status (Finlayson 2016). Wollstonecraft argues that providing women with an education would counteract women's oppression, specifically the sexual double standard. It would also correct the shallowness of "feminine" socialization that made women vain and prepared them for a life of domesticity and little else. She situates her argument within the framework of liberalism, and the late eighteenth century's emphasis on reason and the French "Rights of Man" that countered blind faith in the monarchy and church and culminated in political revolutions in France, Great Britain, and America. Wollstonecraft contends that allowing women to

cultivate their intellect would necessarily make them better wives and more moral and fit mothers of the new Republic's future citizens. In Germany, "Helene Lange and Bertha Pappenheim pressed for equal education and careers for women" while "political liberalism in Scandinavia encouraged women's societies in support of education and the Swedish Society for Married Women's Property Rights" (Freedman 2002).

Although these early advocates for women's rights were forward thinking and radical for their eras, they do not go so far as to lay claim to full civil and political equality with men in their respective discourses. That demand would be more clearly articulated in the 1848 "Declaration of Sentiments," modeled on America's Declaration of Independence and presented at the Seneca Halls Women's Rights Convention in Albany New York, calling for women's "equal treatment under the law, equal right to education, and the equal right to vote" ("Rights for Women: The Suffrage Movement and Its Leaders").

Major Traditions of Feminism: Liberal Feminism, Marxist Feminism, Radical Feminism

Liberal feminism stems from the natural rights doctrine that emerged during the Enlightenment period, and the notion "that all men are created equal, that they are endowed by their Creator with certain unalienable rights, that among these are life, liberty and the pursuit of happiness . . ." (*Declaration of Independence*). Women were not included in this doctrine because of the widely held, albeit mistaken belief that women were biologically, morally, and intellectually inferior to men and lacked the capacity to reason, an essential ingredient for citizenship (Hannam 2012). Finlayson explains that liberal feminism's defining features emphasize: "*Individualism*" (that is, "'autonomy,' 'freedom,' and 'rights'"); '*Distribution*,' "or the equitable distribution of "wealth" as well as "costs"; '*Abstraction*,' wherein "the liberal theorist may begin from a reflection on the *concept* of 'equality' or 'justice'" in order "to produce normative principles"; '*Positivity*,' and the emphasis on what could/should be done; and '*Capitalism*,' by which liberal feminism is

“committed to a capitalist economic framework of one kind or another” (2016). In sum, liberal feminism is tied to a political ideology born of the Enlightenment period, as well as to any of its associated shortcomings. In contrast to Liberal Feminism and its cozy relationship with a capitalist economic structure, Marxist Feminism involves “a commitment to . . . social change; an emphasis on social class and social struggle” while advocating “the revolutionary replacement of capitalist relations of production with communist ones” (Finlayson 2016).

Marxist feminism sees women’s largely uncompensated labor and oppression as the result of class, or economic oppression. Accordingly, this condition may be remedied by replacing capitalism with some form of socialism to regulate production and distribution more equitably, through communism (Cuba, China), or social democracy (Canada, Norway) as examples. From a Marxist perspective, liberal (or mainstream) feminism disregards socioeconomic class differences and focuses too narrowly “on the concerns of (white) middle-class women . . . preoccupied with formal rights and freedoms like suffrage, and neglecting the issue of the material deprivation suffered disproportionately by women” (Finlayson 2016).

Radical feminism: While liberal feminism emphasizes equality and individual rights, radical feminism speaks in terms of “‘oppression,’ ‘domination,’ ‘exploitation,’ ‘violence,’ and ‘subordination,’” and “concrete relations of power” (Finlayson 2016). In particular, radical feminism is concerned with violence against women in its myriad forms (prostitution, pornography, rape, etc.). Both radical feminism and Marxist feminism challenge fundamental sociopolitical and economic structures within which liberal feminists try to work; whereas liberal feminists work to change laws and policies, radical and Marxist feminists see the patriarchal and capitalist systems as fundamentally unjust and incorrigible.

The Waves of Feminism

Scholars have long used the “wave” metaphor to describe modern feminism’s major advances, although the concept can be misleading. For

instance, Laura Finlayson observes how its usage tends to obscure ongoing feminist activity that occurs between the major cultural developments in the waves (2016). Given this caveat, however, the wave metaphor can be a useful way to describe the surge of social and political energy that occurred during watershed moments, resulting in significant gains for women. Feminist history “identifies two key periods of political activism – ‘first-wave’ feminism, c. 1860s to 1920 and ‘second wave’ feminism in the 1960s and 70s” (Hannan 2007). Less politically but more complicated and culturally significant third- and fourth-wave feminisms have their own idiosyncratic features. Although there have been positive outcomes associated with each wave of feminism, oversights and limitations have caused contention. Additionally, to some extent each wave, intending to rectify errors or oversights of the previous waves of feminism, inevitably make their own.

First-Wave Feminism: Suffrage

Although agitation for women’s rights had been simmering for centuries, the Seneca Falls Convention served as a key rallying point and catalyst to modern feminism’s first major wave. June Hannan notes that by this time “women in Europe, America, New Zealand, and Australia” had started organizing “to achieve changes and improvements in the social, political and economic lives of women” (2007). According to Hannan, agitation for suffrage was not an isolated social movement but “part of a much broader campaign – to free slaves, to introduce representative government, to advance the rights of workers and to achieve property reforms” (2007). In America, many activists were also involved with the temperance crusade. Notably, Quakers in America and Great Britain were pioneers in both the feminist and abolitionist movements.

Organizers in the first-wave rallied around the call for suffrage which “held a central place in histories of feminism, especially in Britain and the United States” (Hannan 2007). While necessarily concerned with key issues such as property rights, access to education and employment

opportunities, many American and British activists viewed suffrage as the key to unlocking women's prison of oppression. By contrast, French feminism, which was tied to Republicanism, was slower to unfold and focused on educational and legal reform (Hannan 2007). It cannot be overstated how unconventional, and at times dangerous it was for women activists to venture out of the home and trespass onto public (male-dominated) spaces as these early feminists assuredly did in order to speak out against slavery and on behalf of women's rights. Although lower class women worked in factories, and later in retail, and female slaves worked in the plantation fields, women's socially sanctioned place was in the domestic sphere, and only disreputable women ventured in public alone. Nevertheless, activist women defied social convention, and their methods of activism varied from country to country. Generally, in addition to lobbying political leaders, activists met in small groups, circulated petitions, and wrote and distributed pamphlets and leaflets (Hannan 2007). Under the leadership of Emmeline Pankhurst, founder of the Women's Social and Political Union, and her daughters Christabel and Sylvia, British women resorted to minor acts of violence after years of campaigning with more politic approaches failed to win them the vote. Following Britain's entrance into the war, however, women activists turned their energies to the war effort, and by 1918 Parliament conceded and women (over the age of 30, initially) were granted the right to vote.

A small cadre of activists, in particular Lucy Stone, Elizabeth Cady Stanton, and Susan B. Anthony, organized the Seneca Falls Women's Convention and laid the groundwork for the American feminist movement. Stanton and Anthony headed up NAWSA (National Woman's Suffrage Association) for the express purpose of getting individual states to ratify Suffrage and strengthen their hand for a federal amendment. By design, the American movement for Suffrage did not involve violent methods, although college-educated leaders, in particular Quaker Alice Paul along with Lucy Burns, participated in the British women's movement and were inspired by their zealous sisters' hunger strikes,

and other radical actions that often sent them to prison. Marking the difference in methods, British activists were called Suffragettes, while American activists went by the name Suffragists. Together with Carrie Chapman Catt, British born Anna Howard Shaw, inheritor of Susan B. Anthony's moral mantle (*American National Biography Online*), took over NAWSA and its tedious state-by-state campaign for suffrage. The group splintered, with Paul and Stone working within the CU (Congressional Union) and the newly founded NWP (National Women's Party), to campaign more militantly if not violently for the Susan B. Anthony federal suffrage amendment to the Constitution given the sluggish pace of NAWSA's state by state strategy. Members of the NWP and CU organized a publicity-garnering Washington, D.C. parade for suffrage the day before Democrat Woodrow Wilson's election in March of 1913. Suffragists also brazenly picketed the Whitehouse for months beginning in 1917 and in spite of the US entrance into World War I. Holding banners quoting the Constitution, they exposed the hypocrisy in Wilson's speeches about democracy and the rights of free people being trampled upon while ignoring women's appeal for suffrage. In doing so these "unladylike" Victorian women highlighted their disenfranchisement, drawing both admiration and ire from the public. The "Woman Question" was taking a prominent place in public discourse, given an ethos in which the woman was viewed as the "angel of the house" who had no business engaging in politics in the corrupt, male-dominated public sphere. After hundreds of Whitehouse protestors were arrested and shipped to Occuquam Prison on the bogus charge of obstructing traffic, the battle heated up. The tipping point came with public outrage when the Virginia workhouse's unsanitary conditions and brutal treatment of its prisoners were publicized, in particular, the force-feeding of the women-activists who had gone on a hunger strike to dispute their political arrest. By 1919, the suffrage amendment was on the floor with Wilson's backing, and after heavy campaigning throughout the states it was ratified in 1920. Enfranchisement spread across North America and Europe and was the signature

achievement of first-wave feminism; and similar “campaigns gathered momentum in the inter-war years in Latin America and parts of the Caribbean” as well (Hannan 2007). According to “Key Dates in International Women’s History”: in 1918, women in Russia went on strike for “bread and peace”, an occasion that would later be dubbed International Women’s Day, Women won voting rights in Brazil and Thailand in 1934, in Japan in 1948, and in South Korea and Israel in 1949.

While winning a political voice signified a major leap forward for women, it failed to eliminate the dense layers of cultural and legal barriers to women’s parity with men. For instance, the Comstock Law of 1873, which made contraceptives (along with pornography) illegal in the USA, was not overturned until 1962 in Griswold vs. Connecticut, and then it only applied to married couples. Unmarried individuals would have to wait another 10 years or so for legal access to birth control. Alice Paul and the NWP crusaded for the ERA (equal rights amendment) to redress such persistent legal, social, and economic impediments to women’s freedom and independence in the USA. Their efforts failed. When the ERA was taken up again during feminism’s second wave, it fell three states shy of ratification and remains unratified to this day, a clear indicator of why the work of feminism continues.

Second-Wave Feminism: Sisterhood and the Personal Is Political

The United Nations inaugurated the Commission on the Status of Women in 1947, and in a formal acknowledgement of women’s rights “issued a Declaration of Human Rights” in 1949 (Walters 2005). Several international conferences followed, attesting to the legitimacy and viability of feminist activity that continued churning between the waves. Feminism’s second major wave, or the “women’s liberation” movement, came in the wake of the civil rights movement in the USA, and it both dovetailed and at times, clashed with the gay rights and anti-Vietnam war movements in the late twentieth century. Influential texts of the second wave include Simone deBeauvoir’s rigorous philosophical analysis of

the manufactured nature of women’s secondary status, in which she argues that in spite of the appearance of being natural, “a woman is not born, but made” (*The Second Sex*, 1949); Kate Millett’s *Sexual Politics* (1970), in which she critiques the institution of patriarchy; Germaine Greer’s *The Female Eunich* (1970) that challenges the patriarchal constructs of femininity and womanhood; and Betty Friedan’s *The Feminine Mystique* (1963). Friedan, a founding member of Now (National Organization of Women) identifies “the problem with no name” plaguing American middle-class women in the post-World War II years. Having been actively engaged and gainfully employed in the war effort on numerous fronts, American women were unceremoniously sent back to home and hearth upon their soldier-husbands’ return from the war. As Friedan explains, instead of finding domestic bliss as suburban housewives, many women found themselves depressed and frustrated, since they came to view the private sphere as oppressive, and proof of their secondary status.

When increasing numbers of women did enter the workforce, “they continued to be viewed as women first, workers second” (Freedman 2002). Consigned to low-paying “pink-collar” jobs, as nurses, teachers, clerks, and secretaries, women did not have access to higher paying “male-identified” jobs and professions. They also met obstacles when pursuing advanced education in male-identified fields, such as science and engineering, and had no recourse when they were underpaid or overlooked for promotions or payraises. Women’s desire for better employment and equal educational and financial opportunities was but one major prong of the women’s movement’s second wave. Throughout the western world women also sought sexual freedom, akin to what men enjoyed, and reproductive rights, specifically protection against pregnancy. As well, they sought legal and social protections from sexual harassment, and more crucially, from the domestic and sexual violence that had long been tolerated and gone unaddressed inside as well as outside the home. Given the high number of women’s deaths caused by “back-alley” abortions, access to safe, legal abortion was also high on the feminist

agenda. These issues were identified by women in Great Britain and America who formed “consciousness-raising” groups as a mechanism for identifying “common experiences” of oppression (Walters 2005).

“Sisterhood,” according to Margaret Walters, “was one of the most popular feminist slogans in the 1960s and 70s” (2005), and marches, sit-ins, and social protests became commonplace. In 1968, activists protested the sexual objectification of women at the Miss America Pageant in Atlantic City by throwing girdles and bras into a trash bin, and “300 French women signed . . . ‘The Whore’s Manifesto’ to declare that they had had an illegal abortion . . . followed by a similar public declaration in West Germany”; while women “in Britain, West Germany, and Italy” marched to “‘Reclaim the Night’ . . . to assert their right to be in public spaces in safety after dark” (Hannan 2007). A major outcome of second-wave feminism is the “Take Back the Night” vigils and marches that continue to be held annually in cities and on college campuses throughout the world. The “personal is political” mantra, the title of an article written by journalist Carol Hanisch (1970), aptly captures the era’s spirit, since feminists made the argument that women’s experiences of oppression are not a private issue to be ignored but a political issue requiring widespread cultural changes and significant legal remedy. Liberation was the clarion call in grass-roots campaigns throughout western countries, as Hannan explains: “emancipation implied freedom from constraints and . . . social policies to enable women to achieve their potential” (2007). As a result, a woman’s ‘natural’ role in the home as wife and mother became a hotly contested site that pitted feminists against those who held to traditional womanhood, ultimately contributing to a backlash against feminism. Another area of contention that drew the ire of religious and anti-feminist leaders, and continues to be a chief bugaboo of feminism, was the campaign for legal abortion.

Like feminism’s first-wave, second-wave feminism was largely spearheaded by educated white women, whose cause would ultimately be soundly critiqued for its racial, ethnic, and sexual-identity blindness. Second-wave feminists incorrectly

assumed that the experiences of first-world white women were universal and applied equally to all women. For instance, Margaret Walters notes how “women in the ‘Third World’ have had to confront . . . more intractable problems” having to tackle “sexism in the form of deep-rooted local beliefs and practices, to do with class, caste, religion, and ethnic biases” and often in the context of nondemocratic societies (2005). Additionally, women’s rights in Muslim and African countries have lagged far behind those of western women, especially in theocratic countries, and women of color and lower socioeconomic class in all societies must contend with different priorities largely ignored in feminism’s first two waves. In Mexico, the women’s movement “concentrated on the need for legal abortion, increased sentencing for rapists, and help for battered women” (Walters 2005). Throughout Latin America, feminists “were interested in equal rights and economic redistribution”, and key concerns were with “female illiteracy, and . . . the miserable circumstances of . . . women living in shanty towns and slums” and dying from “botched abortions” (Walters 2005). In failing to consider layered forms of oppression and differences among women, in terms of ethnicity, class, religion, and sexual identity, both first- and second-wave feminism fell short of its equality aims.

In spite of its cultural blindness, however, feminism in western countries made significant inroads on behalf of many women, and on virtually all the aforementioned fronts of women’s liberation. They won landmark legislation, amassed social, political, and economic resources for their cause and weakened the wall between the public and private spheres that served to separate the sexes and fortify the patriarchal sex/gender hierarchy. In the USA, this meant the availability of oral contraceptives in the 1960s, and the inclusion of sexual harassment in Title VII of the 1964 Civil Rights Act. Title IX (1972) guaranteed girls’ and women’s equal access to resources from educational institutions receiving federal aid, enabling them to be involved in competitive sports and earn athletic scholarships. The landmark *Roe v. Wade* (1973) amendment gave American women the right to a legal and medically safe

abortion within limits, while abortion laws throughout Europe were loosened. In addition, contraceptive advice became more widely available, and rape hotlines and crisis centers were established, as were shelters for victims of domestic violence. Finally, Women's History and Women's Studies became legitimate areas of study in the academy. Academic and social programs, as well as social science research proliferated, as did textbooks that acknowledged women's previously unacknowledged contributions to literature, history, and the sciences.

Third-Wave Feminism: Popular Culture and Personal Choice

In spite of three U.N. sponsored international conferences uniting women from around the world during the "Decade for Women, 1976–85", second-wave feminists "in Europe and North America could see that their movement was losing momentum and had become . . . fragmented" (Hannan 2012). In part, this was due to the glaring differences among women that were becoming more evident and contentious, thus challenging the second-wave concept of universal "sisterhood." Feminism's erosion beginning in the 1980s was also exacerbated by the post-structuralist challenge to the universalist notion of "woman" as having one fixed and stable meaning, especially when one's sex is complicated by other aspects of identity (and levels of oppression), such as race or sexual orientation (Hannan 2012). "Queering" or Queer theory in popular culture and the academy emerged from this ethos, destabilizing the heteronormative and fixed categories of gender, sex, and sexual orientation, complicating the feminist cause. Additionally, feminism in the USA found itself in an increasingly hostile political and social climate, partly as a result of its significant gains in the traditionally male workplace and on the reproductive-rights-front. The feminist challenge and changes to the status quo, together with disparaging media hype, such as the women-burning-bras-myth extending from the Atlantic City protest, gave feminism a black eye, and backlash ensued. "Postfeminism" was one response, a view which holds that, contrary to ongoing evidence of sex oppression,

women have achieved equality and so feminism is no longer viable, as expressed in the 1998 'Is Feminism Dead?' *Time* cover story. Fractured and wounded, feminism was hardly dead and the work of women's rights continued on multiple fronts. Nevertheless, feminism found itself in a heightened defensive posture, and an increasing number of women shied away from the feminist label as a result. Because of this, as Hannan explains, the language of activism shifted away from focusing on 'women' to emphasizing the "health and well-being of families", such as "in Latin America where political parties took up feminist demands around employment and social welfare, but were reluctant to pursue reproductive rights, sexuality and sexual violence" (2007). In this fractured milieu, a cultural form of feminism labeled the third-wave flourished.

Beginning in the mid-late 1980s in the USA and Great Britain, the Guerilla Girls, operating anonymously and wearing gorilla masks, engaged in a creative form of guerilla warfare that took on the sexism and racism dominating the art world. They made public appearances, disseminated information, and produced art that appeared on billboards and posters. One classic example is the infamous: "Do women have to get naked to be in the Met Museum?" billboard (and poster) of a supine naked woman wearing a gorilla mask, underscoring the paltry number of art works by women artists in museums relative to art work by male artists, much of which featured naked women. In the early 1990s, the "Riott Grrrls" engaged in a similar form of activism on the punk-rock music front, signifying the birth of the "Girl Power" movement. Reclaiming "girl" from its traditionally demeaning usage, by which men might refer to mature women, and calling forth the more intact self-esteem of pre-puberty girls, these musician-activists tackled the intractable sexism in the male-defined rock music industry head-on. The more mainstream and commercially successful *Spice Girls* in Great Britain came both to epitomize and popularize the "girl power" movement that would, over time, become a template for similar groups such as *Destiny's Child*. Originally, a call to feminist arms, "girl power" has also been co-opted and made into a marketing slogan.

Blogs and zines, or online magazines, including *Bust* and *Bitch*, proliferated during the third-wave period and into the new millennium. Zines became a virtual gathering place for young women to express their anger at the sexist world and talk frankly about “taboo topics, such as rape, incest, and eating disorders”, according to Karen Schilt in “The History of Riot Grrls in Music”. Third-wave feminism was powered by Generation X-ers, who dis-identified from their foremothers’ emphasis on sisterhood, and political action in organizations such as NOW (National Organization of Women) and the feminist publication *Ms.* Whereas second-wave feminists rallied in opposition to the sexual objectification of women and saw “femininity” within patriarchy as male-defined and a cause of their ongoing oppressed status, third-wave feminists claimed both their sexuality and femininity as sources of their power. They also co-opted previously derogative terms intended to keep women in their place, including “girl,” “bitch,” and “chick.” Moreover, unlike second-wavers who critiqued the traditional role of wife/mother as a key site of women’s secondary status, third-wavers instead privileged personal choice, and in this context motherhood might well be a “feminist” choice. More focused on personal empowerment than public policy and collective activism, third-wave feminism found expression in popular culture, and its principles are articulated in such texts as Jennifer Baumgartner and Amy Richards’ *Manifesta*. Within this brand of sex-positive feminism, superstars Madonna, Beyonce, and Lady Gaga could dictate the terms of their hypersexualized musical personas, offsetting charges of their sexual objectification. At the same time, an explosion of T.V. shows and films featuring women as heroes and warriors hit small and big screens: Buffy in *Buffy, the Vampire Slayer*; Ripley in the *Alien* film series, and the crime-fighting “angels” in three film adaptations of the 1970s T.V. show, *Charlie’s Angels*, to name a few. Such pop culture texts, examined through the lens of feminism, also became legitimate areas of feminist intervention and academic scholarship. As with the shortcomings of previous waves, third-wave feminism’s emphasis on individual choice

and expedient connection to pop culture has morphed into a more superficial consumer and celebrity brand of feminism that privileges women of financial means, masking or diluting key feminist principles and aims in the process (Finlayson 2016).

However, the third wave did see increased awareness of and attention to previously overlooked issues of race, ethnicity, religion, sexual orientation, and gender identity, and the ways in which these interact with sex and gender identity and add to women’s experience of oppression.

Fourth-Wave Feminism: Intersectionality and Social Media

With closer attention to the intersection of identities, including race, ethnicity, religion, gender, and sexual orientation, what some are calling feminism’s fourth wave of the new millennium has seen both a re-evaluation of feminism and a resurgence of feminist activity, largely on social media and powered by the internet. According to Ealsaid Munro: “In an effort to draw attention to these axes of difference, contemporary feminists advocate several tactics, including the much-maligned practice of ‘privilege-checking’. As a tactic, privilege-checking is about reminding someone that they cannot and should not speak for others (“Feminism: A Fourth Wave?”). Intersectional feminism reflects this heightened consciousness, and it was perhaps most remarkably displayed in the 21 January 2017 Women’s March on Washington, and in cities around the world, numbering in the millions in protest of the inauguration of Donald Trump, and his perceived anti-feminist and anti-immigrant platform. The march originated with a Facebook posting and was broadcast via social media, and its organizers, speakers, and protestors represented all age groups, as well as a range of ethnic, religious, sexual and gender identities, a glaring contrast to many of the protests and marches in previous waves of feminism. Still being defined, fourth-wave feminism is testimony to the fact that feminism continues to adapt and evolve in response to systematic and pervasive discrimination on the basis of sex and gender, and an increasing number

of men as well as women identify as feminists. In her 2013 TEDx talk, Nigerian writer Chimimanda Ngozi Adichie proudly proclaimed, “We Should All Be Feminists”, following it with an elegantly argued book-length essay in 2014 of the same title, signaling a championing of the once-scorned label. Celebrity feminists have abetted this reclaiming, evidenced in British actor Emma Watson’s work on behalf of the United Nation’s “HeForShe” campaign, and in superstar Beyoncé’s unique, if controversial, blend of black womanhood and third-wave feminism, as declared in the 2014 MTV Awards-show and expressed in her recent music and performances.

Conclusion

Although the feminist label remains controversial, especially among those invested in traditional femininity and traditional roles of men and women, the story of feminism continues. While it is convenient to separate feminism’s waves, it is less that they begin and end, and more that they fold into one another to create energy anew. The feminist work of providing opportunities and advancing equality on behalf of women and girls is ongoing throughout the developed and developing world and is responsive to significant contemporary issues, as well as longstanding ones, such as sex trafficking, rape and genocide as weapons of war, child marriage, and female genital mutilation.

Fertility

Vikas Kaushal
JHPIEGO, Lucknow, India

Synonyms

[Fecundity](#); [Generativeness](#); [Prolificacy](#); [Puberty](#); [Virility](#)

Definition

The state and quality of being fertile and fruitful or an ability of an individual or couple to reproduce healthy offspring in abundance and of the earth to bear fruit through normal sexual activity.

Introduction

The term “fertility” is taken to indicate biological fertility, the capacity to conceive given unprotected intercourse, in contrast to demographic fertility, the actual number of children. It can be looked at from a functional perspective, by the use of biomarkers, or from a mechanistic viewpoint. Functional fertility refers to how easy or difficult a couple find it to conceive, given that they are having unprotected intercourse, and tends to be assessed by looking at how long this takes, since more fertile couples tend to conceive more quickly (Jofee [2010](#)).

Basic Fertility Concepts

Biological conditions that affect fecundity are obviously important in understanding fertility, and since vast majority of people are biologically able to reproduce, and technology affects fertility only if it is used. Basic measures and rates are essential tools for describing what has happened and is happening to fertility. Fertility rates are especially useful because they are, by definition, the number of births per unit of the population;

rates make it possible to compare countries with different population bases and time periods during which the population has changed. Crude birth rate which is the number of live births per 1,000 population in a given year is a rough or crude measure of fertility because the number of births is related to everyone in the population. General fertility rate is the number of births per 1,000 women of childbearing ages, usually considered 15–44 or 15–49. A related but even more precise measure is the age-specific fertility rate, which is the number of births per 1,000 women in a particular childbearing age group. Age-specific fertility rates are usually given in 5-year intervals, from 15–19 through 45–49. Another common measure of fertility is the total fertility rate. The completed fertility rate can be calculated only after women have finished having children. It is the number of births that did occur per 1,000 women during their reproductive years of life (Miller [1987](#)).

Fertility and Economics

Fertility in most of the world has undergone a sustained and seemingly irreversible transition. Today, a low fertility regime is the norm in the developed world, with some regions (particularly in Europe) experiencing sub-replacement fertility. This demographic transition enabled the productivity advances of the Industrial Revolution to be transformed into higher living standards and sustained economic growth. Understanding the revolution in fertility behavior between the Malthusian and the modern eras has therefore been a central research question (Cummins [2011](#)).

Linking the Environment to Fertility

A theoretical framework for understanding how environmental quality is related to fertility behavior (Brauner-otto [2014](#)). (Fig. 1) A vast body of sociological research has provided evidence that community, or context, matters for family and fertility behaviors. Some research has considered how the physical environment or land use patterns are related to fertility. The natural environment is

Fertility, Fig. 1 Heuristic representation of theoretical framework for the effect of poor environmental quality on family and fertility behaviors. Pathways are not

mutually exclusive and diversification involves simultaneous pathways operating. Dashed lines signify conflicting theoretical possibilities

one more dimension of social context likely to influence fertility (Leopold 1986). The economic theory suggests that future changes in climate may substantially influence fertility patterns via the process of structural transformation, among other possible avenues. Noneconomic factors, especially cultural norms, have important consequences for fertility decisions. Economic theories of fertility focus on the desire for a specific level of fertility. Fertility also depends on access to birth control. It is thus possible for climate change to impact fertility through availability of contraception (Casey et al. 2019).

Fetus Development

Christine Lalonde
Laurentian University, Sudbury, ON, Canada

Synonyms

[Developing infant](#); [Early life](#); [Embryo](#); [Ontogeny](#); [Prenatal development](#)

Definition

The continuous growth and development of an embryo and fetus during pregnancy or gestation that begins with fertilization and ends with the birth of an infant.

Introduction

Viviparous animals carry fertilized, developing eggs to term within their bodies and give birth rather than laying eggs (Roberts et al. 2016). The fertilized egg is called an embryo from conception through to 9 weeks of development, when it is then termed a fetus. Gestation is approximately 40 weeks in length, similar to other primate species; however, human infants are not born with the ability to survive on their own and require the care of their parents, defined as an altricial species. Humans often produce a single offspring during a gestational period, trading superfecundity, for variation, heritability, and diversity. The evolutionary pressure to drive the ontogeny of human infants and the stages of development are variable and are widely discussed in literature.

Pre-embryonic Development

A complete gestational period is 280 days, or approximately 40 weeks, beginning with the start of the last menstruation through until birth. The first week of development is called pre-embryonic and goes through six stages of events until the beginning of the second week, where embryonic development continues for 2 months.

The first stage of pre-embryonic development is ovulation, whereby an oocyte, or egg, is released from a female's ovaries by the follicle bursting. If the egg is fertilized, the follicle develops into a corpus luteum, which is important in the hormonal regulation and maintenance of the pregnancy through progesterone production. The second stage is fertilization, which typically occurs in the fallopian tubes, when the head of a sperm fuses with the egg nucleus to form a zygote. After this event, cleavage (cell division), growth, morphogenesis, and differentiation occur throughout the rest of development.

The third stage, cleavage, involves exponential, mitotic cell division that leads into the morula stage – a multicellular ball that becomes an early blastocyst. The blastocyst will become the chorion, a vital component for survival of the fetus. The chorion is one of a few membranes that also

develops alongside of the embryo. The names of the membranes are given based on shelled animal functions but are functionally different in humans. The chorion is the fetal portion of the placenta. The allantois leads away from the embryo, and its blood vessels become the umbilical cord vessels, used to transport blood to and from the fetus. The first membrane to actually appear is the yolk sac and is the first site of blood cell formation. The amnion develops and continues to grow in size with the embryo/fetus and contains fluid to insulate against heat and cold and absorbs shock from maternal movements.

The final stage of pre-embryonic development is implantation. The new embryo implants into the uterine wall through secretion of enzymes by the chorion to digest the uterine endometrium (Norwitz et al. 2001). It also begins to secrete the human chorionic gonadotropin hormone (HCG), which stimulates the corpus luteum in the ovary to produce progesterone, preventing the next menstrual cycle (Staun-Ram and Shalev 2005).

Embryonic Development

During the beginning of embryogenesis, gastrulation starts, where cells begin to change morphological shape and migrate to become three separate layers. These layers, according to evolutionary data, are homologous with other vertebrates and non-vertebrates that also develop into more complex creatures by progressive cellular division and morphological changes (Hall 1998; Nakanishi et al. 2014). The outermost layer is the ectoderm, which will continue to develop into skin, oral, and rectal epithelium, as well as the nervous system. The middle layer is the mesoderm, and it develops into the skeletal, cardiovascular, urinary, reproductive, digestive, and respiratory systems, as well as dermal skin layers. The inner layer, the endoderm, becomes epithelial lining of the digestive, urinary, and respiratory tracts.

By 6 weeks of gestation, these morphological changes are visibly apparent, and the embryo can be recognized as human. The nervous system has

developed significantly and reflexes, such as startle, are present (Schoenwolf and Smith 2000; Solnica-Krezel and Sepich 2012). At the end of the second month, the embryo has undergone massive development and changes and is now considered a fetus.

The Placenta

Among other eutherian mammals, humans produce placental organs to provide an exchange site of numerous nutrients and functions (Burton and Jauniaux 2015). The first lineage of cells from the embryo is destined to become the placenta and is called the trophoblast or trophoctoderm, where troph means nourishment and blast means embryo. Placental organs are pertinent for resource exchanges between the developing offspring and the mother and are present across multiple species, a product of convergent evolution. The placenta is an organ that is grown and shed during the pregnancy and the birth process. It is responsible for nutrient and gas mobility and immune function and acts as a barrier between the mother and fetus. Placentas have evolved independently across multiple animal groups, the consequence of maintaining an egg in the reproductive tract, rather than laying eggs and having the yolk sac and shell provide required nourishment for development and maturation. The mother's new requirement to provide nourishment for herself leads to competition for survival between the mother and the fetus.

Fetal Development

The fetus develops to a limit; human offspring are altricial, especially compared to other primate species, and continue to develop motor skills and neuronal connections after birth. This promotes substantial interactions with caregivers, leading to social learning and variation in behavioral phenotypes. Immaturity at birth allows infants to process specific stimuli, but not at capacity of an adult, hypothesized to permit growth and plasticity of cognitive and behavioral development.

During the third and fourth months of fetal development, cartilage begins to be replaced by bone, increasing the strength and rigidity of structures that will require support or protection when walking, falling, and exploring typical activities. The skin of the fetus is initially covered by lanugo, a soft, furry layer. The lanugo, in turn, is covered by the vernix caseosa, a greasy substance that is produced by fetal sebaceous glands, hypothesized to protect the delicate fetal skin from the amniotic fluid.

The vernix caseosa is uniquely a human developmental feature; however, other animals have different structures with similar functions. The components of the structure, and experimental evidence, indicate osmoregulation is a key function (Hoath et al. 2006). Other hypothesized functions, since the vernix caseosa is hydrophobic, is to protect the infant from detrimental heat loss when in contact with water, while also containing significant water content to moisturize the developing skin (Youssef et al. 2001). Due to its antimicrobial and vitamin components, it has also anti-infective and antioxidant properties and acts as a bacterial barrier with potential wound-healing properties. Evolution of this fetal structure indicates it is adaptive to protect the fetus during gestational environmental exposures, while its innate and adaptive immune responses are underdeveloped.

During the later months of fetal development, 8 and 9 months, the fetus accumulate a lot of fat, which is related to maternal nutrition (Herring et al. 2018). Well-nourished infants store a lot of subcutaneous fat compared to adults due to the consumption rates while growing and learning. Healthy, full-term infants with a good body weight have higher chances of survival (Kessel et al. 1985). Extensive research has been conducted on maternal nutritional deficiency and the outcomes on the infant. Notably, the thrifty phenotype hypothesis was coined by Hales and Barker in 1992, stating stressors acting on the fetal environment are linked to silenced and activated genes that are involved in physiological and behavioral phenotypical profiles. Through permanent and inheritable changes of the fetus' transcription factors, known as fetal programming,

the fetus' physiological and metabolic phenotype becomes adapted to a nutrient-deficient environment. When the fetus is born, if it is raised in a nutrient-dense environment, contrary to the fetal state, the adaptive response becomes aversive – predisposing the infant to obesity, hypertension, and diabetes (Nguyen et al. 2015). This phenotype has been shown to occur in the offspring of multiple species.

Other stressors that can influence genetic phenotype and variability of offspring include maternal illness, psychological insult such as abuse or loss of a family member, injury, or exposure to toxic elements. Each stressor increases maternal endogenous glucocorticoids, which can overwhelm the placental enzymatic barrier and then bind to fetal DNA binding sites, such as CPG islands, modifying genetic activity.

During fetal growth, maternal hormones are also key to the development and survivability of the fetus. Increased levels of progesterone act to decrease uterine motility, smooth muscle contractions, as well as the maternal immune response against the fetus (Druckmann and Druckmann 2005; Di Renzo et al. 2016). Estrogen output increases blood flow to the uterus and lowers arterial expansion, which lowers blood pressure (Mata et al. 2015). Estrogen also stimulates the renin-angiotensin-aldosterone activity that increases water and salt retention, increasing total blood volume.

Birth

The fetus is considered full-term and ready for birth at approximately 40 weeks of gestation. Due to the evolution of bipedalism and larger, complex brains, fetuses have relatively large heads. Fetal heads have developed near the size of the birth canal, which has been preserved in fossil records. The fetal skull has six membranous “soft spots” or fontanelles that permit the skull flexibility to reshape during birth. Unfortunately, some fetuses still outgrow the size of its mother's birth canal and require cesarean sections to ensure the safety of both the fetus and the mother; prior to the development of the

emergent surgery, both the fetus and mother historically died during such a birth.

Conclusion

Different adaptive pressures occur at different points in ontogeny, for example, disruption during organ development versus neural development may lead to lower birth weights and predispositions for adulthood disease versus behavioral changes. The embryonic development is critical to survival and proper organogenesis, whereas the fetal environment can predispose offspring child and adulthood diseases that are adaptive reactions to adverse in utero environments. The fetus does not develop into a completely self-sufficient individual, but to a point that allows live birth considering the female anatomy and the large fetal head. Variability in behavior and physiology and intelligence have evolved to benefit the species in contrast to superfecundity.

Fever

Nicholas A. Davenhill
University of Bath, Bath, UK

Synonyms

Febrile; Pyrexia

Definition

A controlled increase of body temperature, commonly as part of an inflammatory response to pathogens.

Introduction

Fever represents one of a selection of “sickness behaviors” that occur in response to pathogens that have infiltrated the body (Harden et al. 2015). It was itself originally considered a disease, though now has long been recognized as a defense mechanism and an aspect of the immune system. However, the degree to which fever is beneficial or detrimental to the host is still widely disputed (Hasday et al. 2000). Accordingly, the treatment of fever is just as controversial, even after being practiced for thousands of years (Earn et al. 2014).

Matthew Kluger presented some of the early evidence for the benefits of fever in fighting disease. Kluger et al. (1975) gave evidence that lizards injected with *Aeromonas hydrophila* (a bacterium) were more likely to survive when their body temperature was elevated. As such, the increase in heat caused by fever is argued to aid the survival of the host by heightening the immune system and by reducing the growth of pathogens. Recent research, however, suggests that the effect of fever is more complicated than initially considered, as are the consequences for treating it (Harden et al. 2015).

Adaptive Value

Fever has remained a part of the immunological response of both vertebrates and invertebrates (Kluger 1986) for millennia (Evans et al. 2015). Its presence in such a variety of animals is indicative that a febrile response has been present throughout much of evolutionary history, with some estimates suggesting its existence for over 360 million years (Hasday et al. 2000). This extended presence suggests that fever provides an adaptive advantage to the host, as without this survival benefit, it is unlikely that it would be so prevalent today (Kluger 1986).

Further evidence suggesting an adaptive advantage conferred by fever is that the activation and maintenance of a febrile response are energetically costly. For each 1 °C increase in temperature, the body has to increase metabolic rates by 10 % (Kluger 1986). As fever generally increases body temperature by between 1 °C and 4 °C (Evans et al. 2015), this would confer a significant disadvantage to the host if there were no benefits for the energy expenditure.

Though fever appears to benefit human survival in the vast majority of instances, there are situations where a high fever can be dangerous to the host. Such examples include individuals with heart anomalies and pregnant women, the latter being linked to increased rates of birth defects (Kluger 1986). However, these cases are in the minority in comparison to the overall population, and as such fever still provides an evolutionary advantage in enhancing the chances of survival of the host.

Antipyretics

As fever has been present throughout much of our evolutionary history, questions have been raised about whether treating fever is beneficial or harmful to the host's survival. Antipyretics are treatments for fever, most commonly pharmacological within contemporary society, with examples including paracetamol (Harden et al. 2015). These medications aim to artificially reduce fevers and to ease the discomfort in the patient (Zitelli

1991). However, fever has remained a part of the immunological response in a wide variety of species, implying it provides an adaptive advantage. As such, there is potential for antipyretics to negatively impact the immune response of the body by removing the advantages provided by the fever.

Unfortunately, the degree to which the treatment of fever benefits or detracts the host's defense mechanisms is still uncertain, with little definitive evidence to support either conclusion (Harden et al. 2015). The consensus within contemporary research appears to be that, in the majority of instances of fever caused by influenza, there is little evidence to suggest that the use of antipyretics is beneficial (Harden et al. 2015). Conversely, there is also little evidence that the treatment of influenza-caused fever is detrimental other than the potential for altering the inflammatory process (Harden et al. 2015).

There is, however, evidence of a detrimental effect of antipyretic use during the treatment of metastatic melanoma (advanced-stage skin cancer). This is the result of fever enhancing the production of natural killer and T cells during fevers, a benefit which is removed following the use of antipyretics (Køstner et al. 2015). The benefit of a high fever in this example is associated with improved survival rates due to the improved immunological response (Køstner et al. 2015).

Conclusion

Many species have evolved a pyretic response to invading pathogens over a course of millennia. Though fever has a high-energy cost to the host, the immunological enhancement it affords provides an adaptive advantage for survival. However, the overarching benefits and drawbacks of treating fever have received little empirical study. In treatment of conditions such as influenza-based fever, however, the current consensus suggests that there is little benefit gained from treating the fever. There are conditions where fever has been evidenced as boosting the immune response of the host, for example, melanoma and for critically ill patients.

Fiction

Pallavi Rai
CNC Department, All India Institute of Medical Sciences (AIIMS), New Delhi, India

Synonyms

Drama; Fantasy; Imagination; Myth; Storytelling; Untruth

Introduction

There is no doubt fiction makes a better job of the truth by Doris Lessing Fiction is the dream or imagination of the writer consisting of people, events, or places which is not based on facts or history (Abrams 2017). It is literature in the form of prose. In its most narrow usage, fiction refers to novels, but it may also denote any “literary narrative” (Abrams 2017) including novels, novellas, and short stories. More broadly, fiction has come to encompass storytelling with imaginary elements in any format, including writings, audio recordings, live theatrical performances, comics, animated or live-action films, television programs, games (most notably, role-playing and video games), and so on (Oxford Learner’s Dictionaries 2015). Fiction, literature created from the imagination, is not presented as the fact, though it may be based on a true story or situation (Predelli 1997).

Definition of Fiction

According to Oxford dictionary	Fiction is the type of book or story that is written about imaginary characters and events and not based on real people and facts.
According to Merriam-Webster	Something invented by the imagination or feigned.
According to Literary Devices	Fiction is a type of literature that describes imaginary people and events, not real ones.

Concept of Fiction

Etymologically, the word fiction has been derived from Latin word “fictus,” which means “to form.” It consists of stories, novels, and dramas and their construction is based on imagination and fabricated stories and characters (Oxford Learner’s Dictionaries 2015). Fiction contains certain symbolic and thematic features. In other words, fiction narrates a story, which aims at something bigger than merely a story. Fiction may be based on

stories of actual historical events. Although fictitious characters are presented in a fictitious setting in stories and novels, they may have some resemblance to real life events and characters. Writers alter their characters very skillfully when they take them from actual life (Literary Devices Editors 2014).

Function of Fiction

The function of fiction is to entertain, educate, and inspire the readers and the audience. Literature in general and fiction in particular is capable enough to sweep our emotions (Beardsley 1981). Therefore, fiction gives the audience an experience beyond their daily lives. It provides them an insight into the life of the characters, their manners, vicissitudes, and events related to them (Predelli 1997). It also is used to point out the flaws and drawbacks of a society, race, and nation in a manner that it does not touch the boundary of stricture or criticism. Rather, fiction points out drawbacks and then suggests solutions for the individuals and the nations alike. To sum up, fiction can also provide a vent to our pent-up emotions such as hatred, anger, and dislike but in a very light manner without pointing out specific individuals or groups (Literary Devices Editors 2014).

Elements of Fiction

Plot, Setting, Character, Conflict, Symbol, and Point of View, etc., are the main elements which fiction writers use to develop a story and its Theme.

Because literature is an art and not a science, it is impossible to specifically quantify any of these elements within any story or to guarantee that each will be present in any given story (School Work Helper 2010).

1. Plot

Plot is the most important element of a good story. Plot is the order in which things move and happen in a story. It was the carrot on the

string that pulled us through a story as we wanted to see what would happen next.

With that understanding, let's examine the elements ("Reedsyblog" 2018).

- **Exposition:** The de-facto introduction that brings out the story's cast of characters and plants the seeds of conflict.
- **Rising Action:** In which a series of events (usually triggered by an inciting incident) escalates and sets the rest of the story in motion.
- **Climax:** The moment of peak tension in a story – in other words, what everything else builds up to.
- **Falling Action:** The Bridge between the climax and the resolution in which subplots and mini-conflicts are resolved.
- **Denouement:** The wrapping up of the whole story.

2. Setting

The time and place in which the action occurs.

3. Theme

Theme is the main idea that weaves the story together. It is the meaning of the whole story. The term also indicates a message or moral implicit in any work of art.

4. Character

A person, an animal, or an imaginary creature that takes the part in the action of the story.

Character types:

Protagonist – Main character of the story that is most central to the action of the story.

Antagonist – The person or thing working against the protagonist, or hero, in the story.

5. Point of View

The vantage point from which a narrative is told. A narrative is typically told from a first-person or third-person point of view. In a narrative told from a first-person perspective, the author tells the story through a character who refers to himself or herself as "I." Third, person narratives come in two types: omniscient and limited. An author taking an omniscient point of view assumes the vantage point of an all-knowing narrator able not only to recount the action thoroughly and reliably but also to enter the mind of any character in

the work or any time in order to reveal his or her thoughts, feelings, and beliefs directly to the reader (Beardsley 1981). An author using the limited point of view recounts the story through the eyes of a single character (or occasionally more than one, but not all or the narrator would be an omniscient narrator) (Mosley 2019).

6. Style

The author's type of diction (choice of words), syntax (arrangement of words), and other linguistic features of a work.

7. Conflict

Conflict is the struggle between two entities. In story writing the main character, also known as the protagonist, encounters a conflict with the antagonist, which is an adversary. The conflict may be one of six kinds (School Work Helper 2010):

- Character vs. character
- Character vs. nature or natural forces
- Character vs. society or culture
- Character vs. machine or technology
- Character vs. God
- Character vs. himself or herself

8. Symbolism

A person, object, image, word, or event that evokes a range of additional meaning beyond and usually more abstract than its literal significance.

Types of Symbols

Conventional symbols have meanings that are widely recognized by a society or culture. Writers use conventional symbols for reinforcing meanings.

A literary or contextual symbol can be a setting, character, action, object, name or anything else in a work that maintains its literal significance while suggesting other meanings. Such symbols go beyond conventional symbols; they gain their symbolic meaning within the context of a specific story.

9. Tone

Tone is the author's implicit attitude toward the reader, subject, and/or the people, places, and events in a work as revealed by the elements of the author's style.

Genres of Fiction

Genres of fiction are typically defined by their tone and subject matter. The term “genre fiction” generally encompasses popular types of fiction situated within a specific genre outside of standard literary fiction.

1. **Commercial fiction:** It attracts a broad audience and may also fall into any subgenre, like mystery, romance, legal thriller, western, science fiction, etc. Commercial fiction is generally plot driven, and read for entertainment rather than its art (Malatesta 2018). The commercial fiction writer’s challenge is to find creativity within the bounds of genre, while meeting the expectations of a particular audience.
2. **Literary fiction:** It tends to appeal to a smaller, more intellectually adventurous audience. It often focuses on artistry, with the story being driven by character and internal motivations. It presents a broader canvas to writers with endless possibilities for exploring character, theme, setting, and style (Valken 1998).

Other Types of Fiction

1. **Historical fiction:** Historical fiction has characters based on real people and often bases its plots on real-life events. Generally, many elements of plot or dialogue are fabricated by the author, although it is up to the writer how much to invent. For example, *Pink and Say* by Patricia Polacco. Writing historical fiction requires a balance of research and creativity, and while it often includes real people and events, the genre offers a fiction writer many opportunities to tell a wholly unique story (MasterClass 2019).
2. **Literary fiction:** Literary fiction describes mainstream highbrow fiction. Literary fiction encompasses most books taught in high school English courses and most books that are up for major annual prizes like the Pulitzer Prize or Man Booker Prize. Literary fiction

often depicts nuanced themes and incorporates literary devices.

3. **Mystery fiction:** Mystery novels are plot driven thrillers based around a crime or other form of mystery. The story provides clues throughout the story, but the mystery is not typically solved until the end of the story. For example, *I Want My Hat Back* by Jon Klassen.
4. **Science fiction:** Science fiction, abbreviation SF or sci-fi, a form of fiction that deals principally with the impact of actual or imagined science upon society or individuals. Science fiction is a genre of fiction that often depicts stories set against the backdrop of futuristic technology and dystopian societies and it relies heavily on scientific facts, theories (Sterling 2019). Science fiction writers often seek out new scientific and technical developments in order to prognosticate freely the techno-social changes that will shock the readers’ sense of cultural propriety and expand their consciousness (Science fiction 2015). In science fiction stories describe how humans interact with computers, nanotechnology, bioengineering, virtual reality, artificial intelligences, or other parts of technologically driven society. These stories often question the concept of what it means to be human. For example, Movies like *Avengers endgames*, *interstellar*, *Gravity*, *Arrival*, etc.
5. **Children’s fiction:** Children’s literature is a genre of fiction that can range from books for toddlers to full length young adult novels.
6. **Fan fiction:** Fan fiction is a genre of fiction in which fans take source material from existing franchises and then spin them off into separate narratives of their own. The author uses copyrighted characters, settings, or other intellectual properties from an original creator as a basis for their writing. Common bases for fan fiction include novels, movies, and video games. For example, A web series *Fifty Shades of Grey* by E. L. James.
7. **Fantasy Fiction:** Fantasy fiction typically involves a fiction, or untrue, story. The story could not happen in real life and it involves

magic or supernatural powers and most of the time takes place in another world or has make believe characters, such as wizards or dragons in *Game of thrones*.

8. **Realistic Fiction:** It has a story that has believable events and characteristics that could actually happen in real life. It can take place in a real setting; it is not based on history or science. The character seems like real people with real issues solved in a realistic ways. For example, *The Fault in our stars* by John Green.
9. **Romance fiction:** The word “romance” also refers to romantic love. Romance, as pointed out, is a type of fiction, comprising idealized love, chivalry, obsessive association with somebody or some idea, and mysterious adventures. However, Romanticism is a specific movement and period in English literature during which poems, stories, and novels related to Romantic ideas were created. William Wordsworth, P. B. Shelly, Lord Byron, and John Keats are some of the most famous poets and writers of the Romantic period.

For example, *Pride and Prejudice* by Jane Austen, *The Count of Monte Cristo* by Alexander Dumas, etc. (“Roamance Fiction” 2014).

10. **Horror Fiction:** Horror is a genre of fiction which is intended to, or has the capacity to frighten, scare, disgust, or startle its readers or viewers by inducing feelings of horror and terror. For example, Novels like *At the mountain of Madness* by H. P. Lovecraft, *The Bad Seed* by William March, etc.

Formats of Fiction

Traditionally, fiction includes novels, short stories, fables, legends, myths, fairy tales, epic, and narrative poetry plays (including operas, musicals, dramas, puppet plays, and various kinds of theatrical dances and play). However, fiction may also encompass comic books, and many animated cartoons, motion pictures, anime, manga, films, video games, radio programs, T.V. programs (comedies and dramas), etc., digital libraries such as Project Gutenberg,

OPEN LIBRARY, Google-ebook store, Amazon free kindle books make public domain texts more readily available. The combination of inexpensive home computers, the Internet, and the creativity of its users has also led to new forms of fiction, such as interactive computer games, for example, Choice of Deathless or computer-generated comics, for example, Shatter. Countless forums for fan fiction can be found online, where loyal followers of specific fictional realms create and distribute derivative stories. The Internet is also used for the development of blog fiction, where a story is delivered through a blog either as flash fiction or serial blog, and collaborative fiction, where a story is written sequentially by different authors, or the entire text can be revised by anyone using a wiki (“Wikipedia” 2020).

Novel: Novel is a genre of fiction and it is an invented prose narrative of considerable length and a certain complexity that deals imaginatively with human experience, usually through a connected sequence of events involving a group of persons in a specific setting. Within its broad framework, the genre of the novel has encompassed an extensive range of types and styles: picaresque, epistolary, Gothic, romantic, realist, historical. Some of the famous Novels are *Pride and prejudice* by Jane Austen, *The History of Tom Jones, Foundling* by Henry Fielding, *War and peace* by Tolstoy.

Short Story: Short story is a brief fictional prose narrative that is shorter than a novel and that usually deals with only a few characters. A brief story usually 5–20 pages long only has 1–2 main characters and one main setting. There are five key elements that go into every great short story: character, setting, conflict, plot, and theme. For example, *A Haunted House* by Virginia Woolf, *Shooting an Elephant* by George Orwell, *A Sound of Thunder* by Ray Bradbury, etc.

Fable: A fable is a very brief story in prose or in verse that teaches a moral or a practical lesson about how to succeed in life. A fable is a very brief story in prose or in verse that teaches a moral or a practical lesson about how to

succeed in life. For example, *Animal Farm* by George Orwell, Panchtantra stories, etc.

Folk tale: A folk tale is a story with no known author. Folk tales are passed down from one generation to another by word of mouth. They teach lessons and teach you about the consequences of certain kinds of behaviors or attitudes. For example, Cinderella, Sleeping Beauty, Snow White, Rapunzel, etc.

Legend: A legend is a semi-true story, which has been passed on from person-to-person and has important meaning or symbolism for the culture in which it originates. A legend usually includes an element of truth, or is based on historic facts, but with “mythical qualities.” Legends usually involve heroic characters or fantastic places and often encompass the spiritual beliefs of the culture in which they originate. For example, *Ali Baba*, *Fountain of Youth*, etc.

Novella story: A novella is a work of narrative prose fiction, longer than a short story but shorter than a novel. Between 20 and 100 pages, can also be a collection of short stories. For example, Joseph Conrad’s *Heart of Darkness* (1899), *Animal Farm* by George Orwell, etc.

Myth: A myth is a story passed down from generations trying to explain how our world works or how we should treat each other. Myth is a legendary or a traditional story that usually concerns an event or a hero, with or without using factual or real explanations. These particularly concern demigods or deities and describe some rites, practices, and natural phenomenon. Typically, a myth involves historical events and supernatural beings. There are many types of myths, such as classic myths, religious myths, and modern myths. For example, *Romeo and Juliet* by William Shakespeare, *No Second Troy* by William Butler Yeats, *Paradise Lost* by John Milton.

Fairy tale: Fairy tale is an imaginative story or piece of literature told in a variety of media. Stories which are based on magic and fantastical settings, plots, and characters and happy endings. Such stories typically feature entities such as dwarfs, dragons, elves, fairies, giants,

gnomes, goblins, griffins, mermaids, talking animals, trolls, unicorns, or witches, and usually magic or enchantments. For example, Cinderella, *Elves and the Shoemaker*, *Emperor’s New Clothes*, etc.

Epic: Epic refers to genre of poetry. Stories and songs emerged as an oral means of communication and preserving the past: tales of heroic battles or struggles, myths, or religious beliefs. In a time before mass communication, the oral tradition enabled people to pass down stories, most often in the form of rhyming poems. For example, *Buddha*, *Krishna*, *Odysseus*, *Dionysus*, *Zoroaster*, and *Zarathustra* (Literary Devices Editors 2014).

There are many genres of epic like epic fantasy and it describes works of fantasy, such as in J. R. R. Tolkien’s *Lord of the Rings*. Epic fantasy has been described as containing three elements: it must be a trilogy or longer, its time-span must encompass years or more, and it must contain a large back-story or universe setting in which the story takes place. Epic fantasy is not limited to the Western tradition, for example, Arabic epic literature includes *One Thousand and One Nights* and Indian epic poetry includes *Ramayana* and *Mahabharata* (“Wikipedia” 2020).

Difference Between Imagination and Fantasy

Imagination is the experience that one has when they deal with reality, or how they deal with reality, while fiction or fantasy is an unrealistic by product of that imagination.

Imagination is defined by the Dictionary of Psychology as, “the reorganization of data derived from past experiences, with new relations, into present ideational experience.” This means that imagination is often based on real life experiences or a person’s experience with their own reality of life. It is safe to say that imagination is how one views the world. For some it could be a half glass full, while for others it can be a half glass empty. It is often a recreation of the world (Literary Devices Editors 2014).

Fantasy is defined by the Merriam Webster Dictionary as, “something that is produced by the imagination: an idea about doing something that is far removed from normal reality.” So, imagination is what leads one to create a fantasy. Fantasy can also be defined as a branch of fiction that deals with the supernatural such as magic, legends, myth, superpowers, etc. (Menadue and Cheer 2017).

A simple way to distinguish between the two is imagination is the experience that one has when they deal with reality, or how they deal with reality, while fantasy is an unrealistic byproduct of that imagination.

Impact of Fiction on Society

Literature inevitably makes us better human beings. Reading fiction improves our ability to access the mental states of other people, but that is a morally neutral skill, one that can be put to the service of manipulation just as easily as it can be put to the service of philanthropy.

1. **Empathy: Imagining creates understanding**

Reading fiction makes us nicer a more empathetic. An exposure to book really improves our emotional intelligence (Bal and Veltkamp 2013).

2. **Disengagement**

Reading fiction is the best way to relax and get rid of by stress and tension than listening to music, sipping tea, or going for a walk (Mar and Oatley 2008).

3. **Sleep**

Regular readers sleep better. Reading books at night help to relax, increased focus, and improve our sleep pattern.

4. **Improved relationships: Books are a “reality simulator”**

People who read for pleasure have better social skills, better parent child communication, lower rates of depression, dementia, and overall emotional health and relationship.

5. **Readers have less cognitive decline in later life**

When we read a book we use many parts of our brain. We use vivid imagery as well as

memory to follow a plot, or main idea. Reading can be like a mental Gymnastic. Readers experience slower memory declined later in life compared to nonreaders. In particular, later-in-life readers have a 32% lower rate of mental decline compared to their peers (Tamir et al. 2016).

6. **Inclusivity: Stories open your mind**

Reading stories makes us inclusive, tolerant, and open-minded (Bergland 2014).

7. **Vocabulary: Fiction readers build more language**

A 2013 Emory University compared the brains of people after they read fiction (specifically, Robert Harris’ *Pompeii* over nine nights) to the brains of people who did not read. The brains of the readers showed more activity in certain areas than those who did not read – especially the left temporal cortex, the part of the brain typically associated with understanding language.

8. **Creativity: Fictions allows for uncertainty**

Reading boosts creativity via developing imagination and explores our mind. A study published in *Creativity Research Journal* asked students to read either a short fictional story or a nonfiction essay and then measured their emotional need for certainty and stability. Researchers discovered that the fiction readers had less need for “cognitive closure” than those who read nonfiction, and added:

9. **Pleasure: Reading makes you happier**

Survey of 1500 adult readers in the UK found that 76% of them said reading improves their life and helps to make them feel good.

Other findings of the survey are that those who read books regularly are on average more satisfied with life, happier, and more likely to feel that the things they do in life are worthwhile.

Impact of Fiction on Science

Yuval Noah Harari, author of the best-selling book *Sapiens and Homo Deus*, says “Today science fiction is the most important artistic genre. It shapes the understanding of the public on things like artificial intelligence and advance

biotechnology, which are likely to change our lives and society more than anything else in the coming decades” (Wired 2018).

Science fiction occupies a vital role in our society. It makes concrete ideas, hopes, and fears about our relationship to technology, progress, and even to the human body. Science fiction is important for at least three reasons. Firstly, by considering worlds that are logically possible, science fiction can be used to explore our place in the universe and consider fundamental philosophical questions about the nature of reality and the mind. Books that explore these issues include *Flatland* by Edwin Abbott Abbott, *Ubik* by Philip K. Dick, and *2001: A Space Odyssey* by Arthur C. Clarke.

Secondly, science fiction can inspire and motivate number of people to become scientists. Edwin Hubble, who provided strong evidence for the *big bang theory* and was the first person to prove that galaxies exist outside of the Milky Way, was inspired to become a scientist after reading Jules Verne novels (Kupperberg 2004). Astronomer and science fiction author Carl Sagan was influenced by Robert A. Heinlein (Sagan 1979), and theoretical physicist Michio Kaku enjoyed the television show *Flash Gordon* as a child.

Thirdly, and perhaps most importantly, science fiction is the only genre that depicts how society could function differently. This is the first step towards progress as it allows us to imagine the future we want, and consider ways to work towards it. It also makes us aware of futures we wish to avoid and helps us prevent them.

Perhaps the most famous example of the positive effect of science fiction comes from the inclusion of a multiracial cast on the original *Star Trek* television series. When Nichelle Nichols, who played Lieutenant Uhura, was considering leaving the series, civil rights leader Martin Luther King Jr. convinced her to stay (NASA News 2012). King argued that her inclusion on *Star Trek* was important because, as a black woman, she helped represent a future people could aspire to, one where people were judged solely on the content of their character (Kilgore 2010).

Shortly after, Nichols publicly criticized NASA for only selecting white male astronauts, she was invited to NASA headquarters and asked to assist in convincing former applicants to reapply [7b]. This led to the selection of Sally Ride and Guion Bluford, who became NASA’s first female and first black American astronauts, respectively. NASA’s first female black American astronaut, Mae Jemison, directly cited *Star Trek* as an influence [8], and later appeared on *Star Trek: The Next Generation* (NASA News 2012).

As well as considering the effects of current and developing technologies, science fiction can help address long-term problems, such as global warming. It can help with the development of space exploration and prepare us for problems we may not anticipate. One day, time travel, teleportation, or the genetic engineering of humans may happen, we might communicate with aliens, invent simulated realities, or build intelligent robots, and we will be better prepared to deal with these, and other potential dilemmas, if we have already thought about them.

The Windup Girl by Paolo Bacigalupi, *Neuromancer* by William Gibson, *Stranger in a Strange Land* by Robert A. Heinlein, *The Time Machine* by H. G. Wells, *Stranger in a Strange Land* by Robert A. Heinlein.

Related Genres

Utopian Literature: The word utopia resembles both the Greek words “no place,” “outopos,” and “good place,” “eutopos.” A vision of an ideal society. *Utopia* has come to mean a place that we can only dream about, a true paradise. For example, Samuel Johnson’s *The History of Rasselas, Prince of Abissinia* and Samuel Butler’s *Erewhon*.

Dystopian Literature: Dystopia is defined as a society characterized by a focus on mass poverty, squalor, suffering, or oppression. Most authors of dystopian fiction explore at least one reason why things are that way, often as an analogy for similar issues in the real world. Examples of fictional dystopias include Aldous Huxley’s *Brave New World* (1932).

Ecotopian Literature: Where the author posits either a utopian or dystopian world revolving around environmental conservation or destruction. Ecotopian fiction contains visions of a negative, dystopian future that connects with a range of environmental issues. For example, Margaret Atwood's *MaddAddam Trilogy* examines human environmental manipulation and world-wide disaster (Pressley 2015).

Themes of Science Fiction

- Space travel to and from other planets, for example, Stars Wars, Star Trek
- Time travel to the past and future, for example, Back to the future
- Psychological/biological change to man brought about scientific changes, for example, The incredible hulk
- Supernormal Power/talents, for example, Superman, Spider man and Batman
- Science applied to human relations for constructive or destructive purpose
- Battle with Alien life forms, for example, Signs
- Alternate universe, for example, Star War

Best Sci-Fi Movies

- A Clock Orange (1971)
- A Andromeda Strain (1971)
- Solaris (1972)
- 2001: A Space Odyssey
- District 9 (2009)
- The Prestige (2006)
- 12 Monkeys (1995)
- Alien (1979)
- Children of Men (2006)
- Interstellar (2014)
- Arrival
- Her (2013)

Prominent Authors of Fiction

Here is the list of famous fiction writers:

- William Shakespeare (Othello, Romeo and Juliet, Hamlet)

- Agatha Christie (The A.B..C. Murders, The Murder of Roger Ackroyd, A Pocket Full of Rye)
- Barbara Cartland (Love in the Ruins, As Eagles Fly, Messenger of Love)
- Harold Robbins (The Dream Merchants, The Carpetbaggers, Stiletto)
- Georges Simenon (La Premiere Enquete de Maigret, La Marie Du Port, La Veuve Couderc)
- Sidney Sheldon (Bloodline, Rage of Angels, The Naked Face)
- Enid Blyton (Fifth Formers of St. Clare's, Third Year at Malory Towers, The Rockingdown Mystery)
- Danielle Steel (The Long Road Home, Mirror Image, Honor Thyself)
- Dr. Seuss (The Cat in the Hat, Green Eggs and Ham, Oh)
- Gilbert Patten (Frank Merriwell at Yale, Frank Merriwell, Junior's)
- J. K. Rowling (Harry Potter and the Philosopher's Stone, Harry Potter and the Sorcerer's Stone, Harry Potter and the Deathly Hallows)
- Leo Tolstoy (War and Peace, Anna Karenina, Resurrection) (Ranker 2018)

Conclusion

Fiction contributes to a person's moral psychological development and their ability to have empathy or understanding. It enhances our ability to connect with each other. Science fiction can be used to explore our place in the universe and consider fundamental philosophical questions about the nature of reality and the mind.

Field of Behavioral Ecology, The

Emily Lescak
University of Alaska Anchorage, Anchorage, AK, USA

Definition

The study of the ecological and evolutionary basis of animal behavior.

Introduction

Behavioral ecology has its origins in field studies that examined associations among behavior, inter-individual interactions, and the environment (Martin and Bateson 2007). The primary focus is on the study of the ecological and evolutionary basis of animal behavior, specifically the functions of behaviors and their adaptive advantages. Adaptive behaviors allow an individual to increase or maximize its reproductive success, or fitness. Behavioral differences with an underlying genetic basis are subject to natural selection or the differential survival and reproduction of organisms that differ in heritable ways.

Under selection, behaviors best adapted to the local environment increase in frequency over generations relative to less well-adapted behaviors. The behavior that maximizes fitness will depend both on interactions with other individuals as well as the ecological context (environment). Since natural selection can only operate on genetic differences among individuals, for a behavior to evolve, there must be heritable variation in a population and some behaviors must result in greater reproductive success (increased fitness) than others (Krebs and Davies 1993).

However, behaviors do not always vary in ways that are adaptive. Traits may have evolved because they were beneficial in the past, but no longer confer a selective advantage. Traits may also evolve due to neutral processes, such as genetic drift or gene flow. Genetic drift refers to variation in the frequency of genotypes in a small population due to the disappearance of particular alleles, or gene variants, as individuals die or fail to reproduce. Gene flow refers to a substantial change in allele frequencies, typically due to migration.

Proximate Versus Ultimate Causation

Behavioral ecologists distinguish between proximate versus ultimate causation (Mayr 1961). Proximate causes describe how the behavior is performed and provide explanations for it based on immediate causes. Examples include

understanding how a behavior develops, determining what stimuli elicit the behavior, and identifying the genetic and phenotypic factors that underlie behavior. Behavioral ecologists focus primarily on ultimate causes, which take an evolutionary approach to understand why a behavior is performed, proximate mechanisms occur, and organisms respond the way they do. Examples include understanding the adaptive value of a behavior, whether a behavior maximizes fitness, and how behaviors differ among species.

Key Individuals

In 1973, the Nobel Prize in Physiology or Medicine was awarded to Nikolaas (Niko) Tinbergen, Karl von Frisch, and Konrad Lorenz for their research on individual and social behaviors. One of Tinbergen's major contributions to ethology, the study of animal behavior, was to organize the types of questions biologists can ask about behavior into categories: (1) cause, (2) development, (3) function, and (4) evolutionary history (Tinbergen 1963). In one of Tinbergen's studies of survival values, or how an animal's behavior allows it to increase its own or its offspring's survival, he determined that parental gulls remove eggshells from their nests after their offspring have hatched because crows use the white interior of a broken eggshell to find and prey upon unhatched eggs (Tinbergen et al. 1962). Karl von Frisch's major contribution to ethology was in describing the honeybee's (*Apis mellifera*) waggle dance (von Frisch 1967), which is used to relay directions to a patch of flowers to the colony. Konrad Lorenz investigated imprinting behavior, the process by which some birds bond instinctively with the first moving object they see shortly after hatching (Lorenz 1935).

J.H. Crook and David Lack developed a comparative approach in which they associated the behavior of birds with environmental variation. Crook (1964) focused on comparing species of weaver birds in evergreen forests and savannahs. He found that Birds living in forests foraged primarily on insects, were monogamous, and defended large territories, in contrast to the birds

in the savannah, which were granivorous, nested in large colonies, and were typically polygynous. Since food supply in the forest is scattered and unpredictable, reproductive success is limited by the ability of parents to provide food for their offspring. Monogamy is therefore the preferred mating strategy because biparental care is essential for obtaining food. In contrast, in the savannah, food supplies are unstable, but locally plentiful. The polygynist mating strategy used here is likely linked to risk of predation, with the number of mates males acquire dependent upon the number of nest sites they are able to defend. David Lack associated differences in bill morphology and foraging behavior in Darwin's finches in the Galapagos to adaptations to specific food resources (Lack 1947). Their comparative approach highlighted the importance of ecological factors in shaping behavior and the difficulty in distinguishing between correlations and causations in associations between behavior and the environment.

John Maynard Smith coined the term evolutionary stable strategies to describe, using mathematical tools and game theory, how natural selection maintains a balance between opposing characteristics within a species. Game theory analyzes situations in which the best option for one individual depends on the decisions of another (von Neumann 1928). Smith used game theory to demonstrate that natural selection may favor both aggressive and nonaggressive behaviors in a context-dependent manner using a comparison of hawk versus dove strategies. In this example, hawks will always battle over resources, whereas doves will never behave aggressively. A population entirely comprised of doves would be unstable because it would be destroyed by the introduction of a hawk. However, in a hawks-only population, an introduced dove would have a long-term advantage because the hawks' consistently aggressive behavior would lead to frequent injury among hawks, while the dove would avoid harm. Smith demonstrated that a certain ratio of hawks to doves forms an evolutionary stable strategy and that balancing selection is able to maintain both characteristics within a population (Maynard Smith 1976).

Adaptive Behaviors

Behavioral ecologists study the effects of behaviors on foraging, territoriality, mating success, parental care, communication, and likelihood of predation, and how different behavioral strategies contribute to fitness.

Foraging Behavior. Natural selection acts on behaviors that increase feeding efficiency. Foraging includes not only eating, but also searching for, identifying, and capturing food, and involves a trade-off between a food's energy content and the cost of obtaining it. Foragers need to make decisions about what types of food to consume as well as where and how long to search for it. Large food items may contain more energy, but are often more difficult to capture and less readily available than smaller items. Efficient foraging may mean that individuals consistently or periodically maximize energy intake or minimize variation in intake.

Optimal foraging theory states that natural selection will favor individuals whose foraging behavior is as energetically efficient as possible. This theory proposes that animals tend to consume prey that maximizes their net energy intake per unit of foraging time. Shore crabs (*Carcinus maenas*), for example, preferentially feed on intermediate-sized mussels, which provide the greatest energetic gains. While larger mussels provide more energy, they also require considerably more energy to open (Elner and Hughes 1978).

One assumption of optimal foraging theory is that natural selection will only favor behavior that maximizes energetic gains if increased energy is associated with increased reproductive success. For example, direct relationships have been found between net energy intake and reproductive success in captive zebra finches (*Taeniopygia guttata*; Lemon and Barth 1992).

Optimal foraging theory also assumes that foraging behavior is subject to natural selection. In the fruit fly (*Drosophila melanogaster*), variation in a gene called *forager* (*for*) underlies the foraging behavior of larvae. Larvae with the *for^R* ("Rover") allele travel nearly twice the distance while feeding as larvae with the *for^S* ("Sitter")

allele. Experimental studies confirmed that this locus is under selection by demonstrating that individuals maintained at low numbers foraged a shorter distance than those maintained at high numbers. In the low-density group, the *for^S* allele increased in frequency, while the *for^R* allele increased in the high-density group. At low population densities, short foraging trips yield sufficient food, while in high density groups, individuals may have to travel long distances as nearby resources become depleted (Sokolowski et al. 1997).

Optimal foraging theory also has limitations. Animals have needs besides energy acquisition that can conflict with foraging, such as watching for predators, searching for mates, and defending territories or nest sites (Milinski and Heller 1978). Another limitation is that individual differences in foraging success are often due to development, rather than natural selection (Wunderle 1991). Ontological differences in habitat or patch use may be due to dominant adults displacing juveniles, the inability of juveniles to adequately choose patches, diet differences, and/or changing nutritional needs throughout development.

Territoriality. Territoriality refers to the behavior that an individual displays to maintain exclusive rights to an area that contains a limited resource, such as food, nesting sites, or mates. Individuals must make decisions about whether to be territorial and what size territory to defend. Territorial displays and aggressive behaviors are costly because they require energy, can harm the individual, and may alert a predator to an individual's location.

Despite these potential costs, there are benefits to territoriality, including increased access to resources or protection from predators. Since territorial behavior requires time and energy, a territory must provide net benefits greater than those available to an individual that is using the space non-territorially (Brown 1974). For hummingbirds and songbirds, the benefits of territory defense depend upon the amount of nectar in flowers and the birds' ability to efficiently harvest it. If flowers are scarce or nectar levels low, the bird may not get enough energy to offset the cost of territoriality. Alternatively, if flowers are

abundant, then the bird may be able to meet its energy requirements without having to defend a flower patch. Therefore, territoriality is only advantageous at intermediate levels of flower availability and high levels of nectar production (Gill and Wolf 1975).

Territory size may be correlated with food availability, body size, and number of competitors. Territory sizes tend to be smaller when food is more plentiful or nutritious and are often positively correlated with body weight (Schoener 1968). More competitors are attracted to resource-rich areas, making them more costly to defend.

Reproductive Behavior. Reproductive success is determined by an individual's lifespan, mating success, and number of offspring produced per mating. Reproductive behavior is influenced by natural selection and involves searching for a nesting site, finding a mate, and rearing offspring. Reproductive strategies are sets of behaviors that have evolved to maximize reproductive success.

Many species exhibit mate choice, or an evaluation and selection of a potential mate or mates. Since each reproductive event is relatively inexpensive for males, they are able to maximize their fitness by mating with as many females as possible. In contrast, reproductive events are much costlier for females, as they are limited by the number of eggs that they can produce. Females, therefore, have an incentive to be selective in choosing the mate that can provide the best benefit to future offspring (Darwin 1871). Mate choice by both males and females may be found in species with parental care in which both parents contribute equally to the cost of rearing offspring. In some instances, males invest more in reproduction than females. For example, male Mormon crickets (*Anabrus simplex*) transfer a spermatophore to a female during mating that is nearly one-third of the male's body weight (Gwynne 1981).

Competition for mates is termed sexual selection and operates through variance in reproductive success. Selection usually acts more strongly on males because they experience greater variance in success than females (Trivers 1972). Sexual selection leads to the evolution of two types of male secondary characteristics. Intrasexual (male-male) selection influences traits involved in

fighting other males, while intersexual (male-female) selection influences traits important in attracting mates (Darwin 1871). For example, aggressive defense of females can lead to increased male strength and size. In many territorial species, males are considerably larger than females because the largest males have greater mating success. These physical differences between the sexes are called sexual dimorphisms.

Another example of sexual dimorphism includes the horns, antlers, and tusks of males, which may serve as weapons against predators or other males and/or indicators of strength, fighting ability, vigor, and quality. For example, male caribou (*Rangifer tarandus*) with smaller antlers tend to withdraw from sparring matches with caribou that have larger antlers (Barrette and Vandal 1990). In forked fungus beetles (*Bolitotherus cornutus*), males with the longest horns have increased access to females (Brown and Bartalon 1985).

Individuals may select mates based on a variety of criteria. In some species, mates with high fecundity or fertility are preferentially chosen. For example, male Mormon crickets prefer larger females because they carry more eggs than smaller females (Gwynne 1981). Mates may also be chosen based on ability to provide nuptial gifts, typically in the form of food (Vahed 1998). In the hangingfly (*Hylobittacus apicalis*), females tend to only accept males that provide insect prey above a certain size. Because mating occurs while the female is eating, presentation of a larger insect allows for longer copulations and increased likelihood of fertilization. The males who are able to capture larger prey may also be of higher quality (Thornhill 1976).

Mates may also be chosen based on parenting ability. Female threespine stickleback fish (*Gasterosteus aculeatus*) are more likely to lay eggs in nests that already contain eggs (Ridley and Rechten 1981). Having more eggs in the nest reduces the chance that any particular egg will be preyed upon and males who already have eggs in their nests expend more energy defending them than males who are engaging in courtship. In fifteen-spined stickleback (*Spinachia spinachia*), females are more likely to choose males that shake

their bodies frequently during courtship because this behavior is associated with increased fanning of fertilized eggs, which increases rates of successful hatching (Ostlund and Ahnesjö 1998).

Sexually selected traits should be correlated with aspects of fitness such as growth rate, predator avoidance, disease and parasite resistance, and competitive ability (Kodric-Brown and Brown 1984). For example, in zebra finches, carotenoids are associated with increased immune responses (McGraw and Ardia 2003). Females have been found to prefer experimentally carotenoid-enhanced males over controls. Female canaries (*Serinus canaria domestica*) select mates based on their singing ability, which is an honest signal of health (Suthers 1990).

Preference for a specific trait may develop and be maintained if it is correlated with male quality or made males easier to find. If the phenotype has a genetic basis, this advantage will be passed on to future sons and the genes that cause females to prefer the trait will also be favored. This positive feedback is termed runaway selection. A classic example of this is in widowbirds (*Euplectes prognus*; Andersson 1982), in which females select males with long tails. Mating success decreases for males with experimentally shortened tails and increases for those with elongated tails.

However, conspicuous male traits may represent a handicap if they reduce survival (Zahavi 1975). Strong, healthy individuals will produce larger ornaments because they can take on greater handicaps at a lower cost. Handicap size therefore serves as a reliable indicator of quality.

Mates may also be chosen based on access to resources. In green frogs (*Rana clamitans*), females choose males with territories in dense vegetation that is favorable for laying eggs (Wells 1977). In choosing a mate with high status, mating success may be increased because copulation is likely to occur without interruption by other males. In cockroaches (*Nauphoeta cinerea*), for example, dominant males mate more often than subordinates (Breed et al. 1980). Progeny may benefit from their father's status by receiving increased parental care and protection and/or inheriting traits that will enable them to achieve high status as well.

Species use various mating systems to maximize their fitness. In polygynous species, one male mates with multiple females, which increases the variance in male reproductive rates, resulting in heightened selection for increased size and strength (Alexander et al. 1979). Polygyny may be favored if males hold territories that have enough resources for multiple females or in precocious species, in which offspring require little parental care. Polygyny is more common than polyandry, in which females mate with multiple males. One example of polyandry is in spotted sandpipers (*Actitis macularius*), in which males incubate the eggs and care for young, while females mate with multiple males. Monogamy may be favored in altricial species, such as birds, that require two parents to care for young.

Some species of fish (including salmonids and sticklebacks) have two genetically distinct groups of males. One is large and defends territories to acquire mates, while the other, called jacks or sneaker males, is small and remains at the edge of large male territories rather than defending their own. When the territorial male is fertilizing eggs, the smaller jack will dart in and release his own sperm, thus fertilizing part of the clutch.

Parental Care. There is a trade-off between rate of population increase and parental care. R-selected species maximize r , which is the rate of population increase, and minimize parental care, while K-selected species maximize survival and reproduction only when population size is at or near K , which is the carrying capacity, and exhibit greater parental care. Parents typically care for young that face harsh environments, increased predation, and/or intense competition. Females are typically the primary care-giving sex because the costs of producing eggs exceed that of sperm (Trivers 1972). In mammals, females are also responsible for gestation and lactation, which are energetically expensive.

At some point, it becomes more profitable for parents to stop caring for their current offspring and instead devote energy to producing additional offspring, which often results in inter- and intrabrood conflicts (Trivers 1974). Since parental investment is fixed, nestlings may try to

manipulate parents and outcompete siblings to gain a greater investment. For example, in American robin (*Turdus migratorius*) nestlings, begging is positively associated with likelihood of being fed and nestlings respond to increased begging of a sibling by increasing the intensity of their own begging (Smith and Montgomerie 1991).

Social Behavior. There are both costs and benefits to living in groups. Living in groups may help individuals forage more efficiently than they would if they were on their own. Foraging groups may increase the rate at which patches of food are found because individuals learn what or where to eat by observing others. In Great tits (*Parus major*), foraging success is greater in flocks than when birds forage alone (Krebs et al. 1972). Foraging groups can also reduce variation in feeding rate (Baker et al. 1981) if individuals share information about the location of food patches (Krebs 1974). For example, naïve red-billed Quelea (*Quelea quelea*; DeGroot 1980) are able to find resources more often when in the presence of trained birds. Individuals in groups may be able to capture larger prey and have increased success when competing against other species for access to food resources.

Group living may also confer increased protection from predators. Individuals in groups may shelter themselves by placing other group members between themselves and a predator and increased group sizes will decrease the likelihood of any one individual being preyed upon. Group members may be able to detect predators more efficiently than solitary individuals. When individuals pay attention to other group members' behavior, the entire group is alerted if one individual detects a threat. Certain individuals or species (in interspecific groups) in a group may serve as lookouts. For example, in the Amazon, white-winged shrike-tanagers (*Lanio versicolor*) act as sentinels in canopy flocks, while bluish-slate antshrikes (*Thamnomanes schistogynus*) serve as sentinels in understory flocks (Munn 1986). These species are typically the first to alarm when predators approach, alerting other species of imminent threat. Group members may also cooperate to drive predators away. Nesting bluegill sunfish

(*Lepomis macrochirus*) work together to keep bullhead catfish from preying on their eggs (Gross and McMillan 1981).

There can also be drawbacks to living in a group. Group members may have to expend energy to maintain high status positions (Taborsky and Grantner 1998), experience reduced fitness (Hotker 2000), compete with each other for access to food (Scheel and Packer 1991), and be more vulnerable to infection (Alexander 1974). If groups get too large, individuals may become more vulnerable to predators. For example, wolves (*Canis lupis*) can capture caribou in large herds more easily than those in small herds, implying that individuals in large groups may not be able to detect approaching predators (Crisler 1956).

The optimal group size will vary among habitats and species and the group size that is optimal for one individual (a dominant one or an adult) may not be the same for another individual (a subordinate or a juvenile). Individuals should choose group sizes and habitats that maximize fitness (Fretwell 1972). The optimal group size is determined by comparing the fitness of the lowest-ranking group member to the fitness that the individual would have if they were solitary and in a poorer habitat.

Dispersal. Species may exhibit two types of dispersal. Natal dispersal refers to movement from the birth site to location of reproduction, and breeding dispersal is the movement of adults between breeding attempts. Dispersal is energetically costly and may expose the individual to predators. However, it can be beneficial for a variety of reasons. Innate dispersal refers to a genetic predisposition to disperse and is common in animals such as the spruce grouse (*Falcipennis canadensis*), in which the young disperse without receiving cues from their parents (Keppie and Towers 1992). Dispersal also has a genetic basis in fire ant (*Solenopsis*) queens, in which individuals carrying one genotype pursue new nesting sites, while individuals with the alternative genotype are more likely to return to their natal nesting place (DeHeer et al. 1999). Proximate causes for dispersal include responses to environmental factors, such as the absence of or competition for

suitable resources. Ultimate causes of dispersal include inbreeding avoidance and competition for mates or resources.

In birds and mammals, dispersal is sex-biased. Dispersal may be costly to female mammals because their reproductive success is limited by nutritional constraints, while males are limited by the number of females with whom they can successfully mate. Female mammals may benefit more from philopatry, remaining in or returning to their birthplace to breed, because they would be more familiar with resources, whereas males may benefit from increased dispersal because they would have greater access to mates. Female Belding's ground squirrels (*Uroditellus beldingi*) remain in close proximity to their birthplace because they need a territory in which to rear their young and their mothers are able to help them defend their territories (Holekamp 1984). Similarly, female lions (*Panthera leo*) remain near their birthplaces so they can benefit from access to familiar hunting grounds and safe places to rear offspring (Pusey and Packer 1987), while dispersing male lions are able to mate with non-relatives (Hanby and Bygott 1987). In birds, males may be more successful at establishing territories in their natal area, whereas females may benefit from the opportunity to disperse to choose different mates.

Cooperation. Cooperative behavior evolves to provide a benefit to another individual and increases the fitness of both the giver and the recipient. Rodents, mammalian carnivores, and birds with young that require a high degree of parental care may engage in cooperative breeding, in which non-breeding adults contribute physically, but not genetically, to rearing young. Helpers may increase offspring survival by providing additional protection from predators and more food. Helpers' fitness may increase if individuals are able to learn parenting behaviors or inherit a territory.

Cooperation may also be inter-specific. Aphids (*Aphidoidea*) secrete a liquid that ants (*Formicidae*) like to eat. In exchange, the ants protect aphids against predators and will sometimes raise their eggs and larvae inside their colony (Dawkins 1977). Some fishes, such as the

goby (*Gobiidae*), will feed on ectoparasites of other fish.

Communication. Communication describes an action of one organism that changes the behavior of another organism. Communication can increase fitness if a stimulus or signal provides an advantage to either the signaler or its group.

Information may be communicated using visual, chemical, tactile, and/or auditory cues. The type of communication used by an individual is dependent upon their life history characteristics and environment. Both nocturnal and diurnal species use auditory cues to communicate. However, nocturnal animals are more likely to use olfactory signals that can be detected in the dark, while diurnal animals rely more heavily upon visual cues.

Individuals communicate to attract mates, scare off predators, and locate food. For example, male Mallorcan midwife toad (*Alytes muletensis*) calls stimulate the reproductive physiology of females (Lea et al. 2001). To alert gravid females that they are ready to reproduce, male threespine stickleback fish engage in elaborate courtship rituals that entice females to deposit eggs in their nests. Honeybees will engage in waggle dances to direct colony members to the location of food (von Frisch 1967). Signals also help individuals conserve their energy. For example, roaring in male lions and erection of spines in stickleback are less energetically expensive behaviors than attacking invaders.

Conclusion

Behavioral ecology has a rich history of study dating back to Darwin's observations in the 1800s. Researchers focus on the purposes of behaviors and their adaptive advantages. Adaptive behaviors with a heritable basis increase individuals' reproductive success and are under positive natural selection. The field focuses on ultimate causes of animal behavior, such as whether they maximize fitness and how behaviors vary among species. Foraging efficiency, territoriality, mating strategies, parental care, and communication are all types of behaviors that influence survival and reproductive success across species.

Definition

A multidisciplinary field that examines the similarities and differences in the behavior of organisms with special emphases on the development and evolution of the behaviors.

Introduction

Modern comparative psychology, one of the interdisciplinary fields in psychology, developed from the convergence of a number of separate disciplines including ethology, behavioral ecology, psychology, systematics, and genetics (Gariépy 1998). Examining questions of functional adaptiveness, development, and evolution of behavior, comparative psychology incorporates all aspects of a living being: anatomy and physiology, genetics, affect, cognition, and sociality. This diverse field explores questions of behavior, behavioral development, cognition, communication, emotion, learning, mating, memory, motivation, perception, social relationships, spatial navigation and orientation, parental behavior, and many other specific topics. Comparative psychology incorporates a specific method of investigation in which multiple species are compared systematically to address various questions about evolution and shared phylogeny.

History

References in which the history of comparative psychology is described generally point to the publication of Charles Darwin's (1809–1882) two most influential books, *On the Origin of Species* (1859) and *The Expression of the Emotions in Man and Animals* (1872), as the pivotal moments in which animal behavior was brought into mainstream science (e.g., Greenburg and Haraway 1998; Siiter 1999; Slater 1999). Focused on the importance of the similarities in physical, behavioral, and emotional attributes of individuals of common descent, Darwin's ideas impacted the fields of biology and psychology.

This fledgling field of animal behavior was expanded by George John Romanes (1848–1894), a British naturalist and staunch admirer of Charles Darwin and his ideas. Romanes applied Darwin's idea of evolution and its mechanism of natural selection to mental processes, including higher-order thinking (e.g., planning, comparing, and contrasting), proposing that intelligence ranged in complexity from the least complex

animals to the most complex animals (i.e., humans) (Gariépy 1998; McInnis 1998; Siiter 1999). This gradient approach to the spectrum of mental abilities across species influenced the fields of learning, comparative cognition, and developmental psychology. A proponent of the anecdotal method, Romanes developed his hypotheses from individual pieces of evidence obtained from firsthand experiences, secondhand stories, or descriptions of interesting and clever behavior across many species of animals. Unfortunately, this data collection method is subject to inherent biases as humans often attribute human characteristics to animals (i.e., anthropomorphism), endowing animals with characteristics that may be more than necessary.

C. Lloyd Morgan (1852–1936), a British psychologist, close friend, and critic of Romanes, emphasized the importance of objectivity and empiricism when interpreting animal behavior. While agreeing with the possibility that mental processes also evolved, Morgan reminded early and future comparative psychologists to avoid explaining behavior using higher mental processes when lower-level psychological processes could account for the behavior (Gariépy 1998; Greenberg and Haraway 2002; McInnis 1998; Siiter 1999). This rule is known as Morgan's Canon as Morgan was the first to apply this idea of parsimony to animal behavior (Siiter 1999).

Following this early venture into comparative psychology and the importance of comparing different animal species using objective, empirical methods, the psychology-based field of behaviorism advanced comparative psychology. Focused on uncovering the general principles of learning and motivation, behaviorists such as Ivan Pavlov (1849–1936), Edward Thorndike (1874–1949), and John B. Watson (1878–1958) continued to utilize characteristics of comparative psychology by emphasizing the specific mechanisms and the development of behavior (Greenberg and Haraway 2002; Siiter 1999). Although the era of behaviorism examined learning and motivation in several species (e.g., rats, *Rattus norvegicus*; dogs, *Canis lupus familiaris*; cats, *Felis catus*), the behaviorists were heavily criticized for their lack of diversity in topics and species (reviewed by Gariépy 1998; Greenberg and Haraway 2002).

While comparative psychology was growing in America, the field of ethology was emerging from biology, led by Konrad Lorenz (1903–1989), Nikolaas “Niko” Tinbergen (1907–1988), and Karl von Frisch (1886–1982), among others. Emphasizing the importance of instinct or innate behaviors, biological explanations, and naturalistic field studies, ethologists focused on the adaptiveness of particular behaviors and the evolution of those behaviors (Greenberg and Haraway 2002; Siiter 1999).

Key Concepts

Anthropomorphism Anthropomorphism is the attribution of human qualities to nonhuman animals. Early studies in comparative literature relied heavily on anecdotal evidence of humanlike behavior in animals. Scholars such as Romanes and Buchner focused on three main areas: complex reasoning, social behavior, and social emotions (such as sympathy, shame, jealousy, and humor). Lloyd Morgan's Canon (1894) emphasized parsimony, urging scientists to limit their conclusions to the psychologically simplest process consistent with the data. With Morgan's Canon, anthropomorphic explanations were viewed with more skepticism but still held a place in the field. It was during the 1920s, with the rise of behaviorism and the biological perspectives of ethology, that anthropomorphism started to be viewed as unscientific and even a fallacy of reasoning. Animal behavior research and ethology focused on objectivity and qualitative data. Research on animal emotions, especially social emotions, and complex reasoning was rejected as inherently flawed by anthropomorphic assumptions. Curiously, zoomorphism, the application of animal motivations to explain human behavior, held some popularity from the 1960s to the 1970s.

As behaviorism receded in psychology, comparative research on cognition, problem-solving, and emotions in animals resumed. While anthropomorphism is still widely considered by many to be invalid scientific reasoning, a minority perspective on the values of anthropomorphism is

gaining strength. As a well-regarded primatologist, Frans de Waal, PhD writes in his 1997 article, *Are We in Anthropodenial?*, “As soon as we admit that animals are far more like our relatives than like machines, then anthropodenial becomes impossible and anthropomorphism becomes inevitable – and scientifically acceptable” (de Waal 1997). However, not all anthropomorphism is useful, as also noted by de Waal. Through hours of observation, a primatologist knows that a seemingly grinning chimpanzee may be aggressive, just as many pet dog owners can differentiate a snarl from human smiling. “A careful observer may thus arrive at an informed anthropomorphism that is at odds with extrapolations from human behavior.”

Anthropocentrism Anthropocentrism is the tendency to interpret the behaviors, emotions, or cognition of other animals using humans as a reference point. Anthropocentric, meaning human centered, perspectives take on four major forms in comparative psychology. First, studies can directly compare animal cognition, emotion, and behavior to humans. Often humanlike outcomes are considered the standard for success. Traditional anthropocentric ideas used the phylogenetic scale to legitimize their perspective. The phylogenetic scale, or *scala naturae*, is the notion of a linear ladder of evolution from low-level worms, fish, and reptiles to more complex birds, mammals, and primates. Humans were viewed as the pinnacle of evolution. While terminologies like “higher” and “lower” animals remain, modern conceptualizations of phylogeny see evolution along distinct branches, rather than a linear progression.

Second, researchers can latently interpret behavior as more sophisticated or desirable, when it is merely more humanlike. Ecological and adaptation approaches offer alternatives to these aspects of anthropocentrism. For example, early research on memory examined if animals formed abstract categories, similar to humans. Ecological approaches ask different questions, examining how animals use their memory for tasks such as foraging, traveling long distances, or managing complex social hierarchies.

Third, research designs and research questions can neglect to consider the different sensory experience of animals. Jakob von Uexküll (1957) proposed the idea of “*umwelt*,” taken from the German word for “environment” or “surrounding world,” to remind researchers to consider the “subjective experiences” of all species and individuals within a species even when they are living in the same environment. When the sensory abilities and perceptions of species other than humans are ignored, the behavioral and social repertoires remain incomplete. For example, many insects perceive ultraviolet waves that emanate from potential food sources or from conspecifics. These abilities were untapped initially because researchers limited their measures to the human visual perception range, forgetting that some species have extrasensory abilities. Infrasonic communication between elephants over long distances (Payne et al. 1986) and ultrasonic communication for some dolphins and whales (e.g., Samarra et al. 2010) were only discovered once equipment with the appropriate measuring range was utilized.

Finally, research in comparative psychology can be considered anthropocentric if its expressed goal is to further the understanding of human psychology. Advocates of comparative psychology suggest that animals should be studied for their own sake rather than to advance the understanding of humans.

Ethology and Tinbergen’s Four

Questions The Dutch ethologist and zoologist Nikolaas Tinbergen was one of the most influential figures in the ethological branch of comparative psychology. He believed that an organism’s behavior can be assessed through complementary perspectives expressed as four questions that he proposed to guide ethological research, two assessing the *ultimate* causes of behavior (e.g., What is the evolutionary function of this behavior?) and two assessing *proximate* causes of behavior (e.g., What environment or motivation triggers this behavior?) (Tinbergen 1963).

Questions about ultimate causes of behavior center around the evolution across phylogenetic backgrounds and the adaptive function of a behavior. A researcher who is interested in the

phylogeny of a targeted behavior may direct the attention toward the understanding of the patterns of that behavior and may be interested in conducting a cross-species comparison to determine whether the behavior of interest is shared and among which animal species it is shared. A researcher who is interested in the *adaptive function* of a targeted behavior may want to examine how a targeted behavior is adopted by the animal to efficiently use its external environment, to establish social relationships with its conspecifics, and to successfully reproduce. Phylogeny and adaptive function are the two levels that constituted Tinbergen's theory of *ultimate* causes of behavior.

Questions about proximate causes encompass biological *causal mechanisms* and the development of a specific behavior (*ontogeny*) (Bateson 2014; Papini 2010). Answers to questions that address phylogeny and adaptation of behaviors do not provide information about the emergence of behavioral skills that are necessary to perform a specific behavior. A researcher who is interested in the *mechanism* that regulates a behavior may investigate the integration of sensory and motor information, the various functions of the brain and the influence of those functions on behavior, and the external factors that determine the occurrence of a behavior. A researcher who is interested in the *development* of a particular behavior may explore the influence of age, experience, presence of social partners, type of interaction, observational learning, and other factors that could contribute to changes over time of the behavior under study.

Phylogeny Versus Ecology To the extent that comparative psychology is facilitated by the comparison of psycho-behavioral phenomena across species, the issue of choosing a comparison species or comparable behaviors remains central dilemmas. Traditional comparative psychology seeks to determine how the mechanisms that guide behavior evolved and how it is distributed across the animal kingdom, Tinbergen's question of *phylogeny*. In studying behavior across related species, researchers aim to reconstruct the origin of the behavioral mechanisms and perceptual responses in evolutionary history. Behaviors are

considered homologous if they share a similar origin or a common ancestry.

The social ethology (sometimes called socio-ecology) perspective shifts the focus from historical ancestry to the modern ecology of species. Social ethologists see shared environmental pressures as more important to understanding behavior and social structure than evolutionary history. Comparisons based on phylogeny as well as shared ecology are prevalent in modern comparative psychology.

Evolutionary-Developmental Framework:

Nature Versus Nurture Comparative psychology searches for the genesis of behavior, evolutionarily as well as through the developmental lifespan of individuals. Particular emphasis has been placed on early development in an effort to discern innate from learned behavior. Scholars of instincts focus on innate behavioral responses present at infancy, such as imprinting in birds. Ethologists emphasized the role of "nature," meaning innate instinctual responses. Behaviorists focused on "nurture," studying infancy and early development as a "blank slate" for learning. During this time, the diversity of species studied by comparative psychologists diminished in favor of a model species approach. Learning was theorized as a universal process following general rules that was relatively invariant across species.

Modern comparative psychologists study both the innate and learned influences of behavior, as well as the complex interplay between the two influences. Comparative psychology studies an ever-increasing number of diverse species and behaviors. Rather than focusing on classifying a behavior dichotomously as innate or learned, comparative psychologists use the onset of a behavior during the developmental process to explain behavioral patterns.

Methodology

Comparative Approach Sharing its name with the discipline, this approach incorporates the comparison of behavior and traits between individuals

that share a common ancestry or traits that emerged due to convergent evolution (Hailman 1998). A current example is represented by the work of Elisabetta Palagi and colleagues on the presence and nature of play across a number of mammals (Palagi et al. 2015). Their work has indicated that, in primates, egalitarian species display more social play and tolerance along with a greater use of play signals often expressed in facial expressions (e.g., Ciani et al. 2012; Scopa and Palagi 2016). The comparative approach is also used to examine the behavior and traits of extant species to make generalizations about extinct species (Hailman 1998). Using fossils and contextual clues, paleontologists can draw inferences about prey-predator relationships, physical movement, parental care, foraging habits, or degree of sociality of extinct species. When combined with behavioral and physiological information from currently living descendants, scientists can model various processes by which a particular lineage evolved. The comparative approach addresses questions regarding the relationship between genetics and environment, the pressures that led to changes in ancestral species to the current descendants, and evolved differences in sociality and adaptability to different environments. Comparing across species was the primary method used during the infancy of comparative psychology. However, when the behaviorist approach gained momentum, the comparative method was reduced to a narrow set of species that were easily managed and experimentally manipulated in laboratories (Gariépy 1998). The emergence of ethology encouraged scientists to resurrect the comparative method using more naturalistic contexts and methods (Gariépy 1998).

Experimental Approach One of psychology's traditions is to conduct experimental-based research in which an independent variable is manipulated under controlled circumstances to assess the resulting effects on a dependent variable. While this method allows for causal conclusions, it also limits the generalizability of the findings due to the artificial setting created during experimental conditions. The experimental

approach was especially popular during the height of the behaviorists when most of our current knowledge of motivation, classical conditioning, operant conditioning, memory, and other learning phenomena was derived from laboratory-based experiments using a narrow range of species, such as albino rats (*Rattus* sp.; e.g., Watson, Thorndike), zebrafish (*Danio rerio*; e.g., Bitterman), and pigeons (*Columba* sp.; e.g., Skinner, Wasserman). Considered a major limitation by more traditional comparative psychologists and ethologists, the experimental approach was criticized for its narrow scope and limited ability to approximate naturalistic conditions especially with semi-domesticated or laboratory-bred species (reviewed by Beach 1960; Gariépy 1998; Haraway and Maples 1998). Despite these limitations, experimental studies were and remain critical in understanding the causal mechanisms of behavior. For example, research conducted on the mating preferences of male and female lizards has tested experimentally a number of mechanism and phylogenetic hypotheses by experimentally manipulating different physical attributes for males and females and testing mate preference (e.g., Keren-Rotem et al. 2016; Sacchi et al. 2015; Swierk et al. 2013). These tests have been conducted both in the field and in the laboratory with wild-caught and bred lizards using both natural variation in live animals and experimentally manipulated models.

Ethological Approach In response to the artificial contexts of experimental research, ethologists emphasized the importance of examining behavior within naturalistic settings, arguing that the laboratory setting constrained the production of natural behavior (reviewed by Gariépy 1998; Haraway and Maples 1998). Focused on questions about the function, the development, and the evolution of a given trait or behavior, ethologists approached these questions using closely related species in their natural habitats (Gariépy 1998; Haraway and Maples 1998). Early ethologists primarily used observational techniques to study animals in their natural habitat. Looking for similarities between individuals of a species, ethologists mapped species-typical behavior

using very detailed observation notes and behavioral checklists called ethograms in completely uncontrolled environments. Jane Goodall's work with the chimpanzees of Gombe (Goodall and Pusey 2016) and Dian Fossey's work with the mountain gorillas of Africa (Fossey 1970) are prime examples of the importance of conducting observational research over long periods of time. A consistent presence in the field allowed the animals to acclimate to their presence and provided both researchers with opportunities to experience and observe behaviors that were unparalleled in laboratory or zoological settings (e.g., holding infants, alliance formation, homosexual behavior). Contemporary ethologists incorporate both observational (paper and electronic behavioral ethograms) and experimental techniques (e.g., playbacks, model simulations, cross-fostering) into studies today to investigate traditional topics of species-typical behavior like courtship, parenting, foraging, and locomotion as well as more psychologically oriented topics, such as empathy, problem-solving, memory, play, and cooperation (e.g., de Waal 2008; Osvath et al. 2014; Plotnik and de Waal 2014).

Extensions of comparative psychology and ethology included E.O. Wilson's (1929–current) sociobiology, which emphasized the biological basis and evolution of social behavior and ultimately developed into behavioral ecology (e.g., Krebs and Davies 1978) and evolutionary psychology (e.g., Cosmides and Tooby 1987). Behavioral ecology is the scientific study of behaviors that evolved due to ecological pressures (Krebs and Davies 1978) while evolutionary psychology focuses on the adaptiveness of psychological and mental processes displayed by humans and our ancestors as influenced by evolution (e.g., Cosmides and Tooby 1987).

Today, all of these disciplines are actively investigating a diverse set of questions with each discipline focused on a particular aspect of behavior, whether it is problem-solving, cooperation, migration, foraging habits, learning, parenting, aggression, communication, sociality, or mating. Comparative psychology exists in many forms, including behavioral neuroscience, animal science, zoology, behavioral ecology, and ethology

to name a few. Each field emphasizes different methodologies including laboratory-based experiments, field-based observations, and naturalistic-based experiments. Some fields focus on specific animal models, while others incorporate more diverse species that systematically vary across phylogenetic background. And, within each field, researchers may focus on proximate questions of ontogeny and mechanism or on ultimate questions of phylogenetic evolution and functional adaptation.

Conclusion: The Future of Comparative Psychology

As discussed here, a clear definition of comparative psychology has been challenging to determine, partly due to the fact that this branch of psychology is one of the oldest fields within the study of psychology (Papini 2010). Since the controversies of the mid 1900s between psychologists and biologists interested in the study of animal behaviors, Tinbergen's approach (1963) has been the most closely related method used to conduct comparative research. Questions that address how the causes of specific behaviors relate to the phylogeny and adaptive significance of behavior, whereas questions that address how individuals come to adopt different behaviors dependent upon the situation relate to the mechanism and the development of behavior (Tinbergen 1963). Comparative psychology is the discipline which integrates these aspects of behaviors and examines the related questions utilizing the knowledge of psychological theories and the understanding of behavioral neuroscience, developmental biology, behavioral ecology, and evolutionary principles (Papini 2010). The interdisciplinary nature and integrative perspective that distinguish this branch of psychology may be the fundamental reason for recent concerns about the future of comparative psychology as addressed by Abramson (2015). The majority of undergraduate psychology programs in the United States do not include comparative psychology in their academic core classes, and very few of these programs offer

an academic course identified as *comparative psychology* (Abramson 2015). Within the field of psychology, the comparative method has been adopted by the majority of the subfields, such as developmental psychology, cognition, social psychology, and psychology of learning. For both human and nonhuman animal studies, comparative psychology is utilized to compare behaviors across various stages of development, to investigate interspecies differences and commonalities in cognitive abilities, to examine the influence of culture and social environment on an individual's behaviors, to study behavioral variations dependent upon different life experience. This research approach has extended to various biological sciences, including developmental biology, comparative physiology, comparative anatomy, neuroscience, comparative neurobiology, and animal science, which use the comparative method to approach their questions. Despite the concerns exposed by Abramson (2015), the majority of comparative psychologists, who responded to Abramson's commentary, agreed that comparative psychology, today, must be seen as a perspective rather than a discipline on its own (Chiandetti and Gerbino 2015; McMillan and Sturdy 2015; Osvath and Persson 2015; Vasconcelos and Pandeirada 2015). It is an interdisciplinary approach that teaches critical thinking skills through cross-discipline training. It is the bridge that brings biological and social sciences together with the goal of providing a more complete knowledge of principles that govern behaviors and developing novel ideas that advance apparently distant research fields.

Definition

The scientific study of human language(s) and/or the human language faculty.

Introduction

“Asking a linguist how many languages they speak is like asking a biologist how many pets they have.”
–Unknown

Comparing biologists with linguists illustrates one of the more common misunderstandings about linguistics: although language is the *object* of study in linguistics (like living things are the object of study in biology), the relationship between linguists and language is most often one of observation rather than ownership or fluency. Using a language and being able to describe how a language works are two very different things: for example, if you're reading this, you are presumably fluent in English. But, unless you've studied linguistics before, it's unlikely that you can say whether the 'p' at the end of the word *stop* is aspirated or not. (For interested readers, in the case of the word *stop*, the p is not aspirated; say

pin and *stop* with your hand directly in front of your mouth. When you say *pin*, there will be a puff of air – this is aspiration, which is absent in *stop*.)

This highlights another major misconception about linguists and linguistics: the vast majority of linguists are concerned with observation and description, not with policing and correction. Linguists want to know why languages work the way they do, revealing why language in general works how it does, and illuminating new facts about the human mind in the process. Grammatical ‘errors’ (like stranding a preposition at the end of a sentence) are the sorts of phenomena that linguists are especially fond of. The types of errors we make in speaking or writing can be revelatory about how we process language in the brain (Harley 2013) and can even indicate shifts in the way a particular language works. Speakers of Middle English would find our Modern English “ungrammatical” to say the least – it might even be incomprehensible in some cases. However, this doesn’t mean modern English is *wrong*, only that it has changed over time (and space, e.g., British vs. American English). As a culturally transmitted phenomenon, languages are constantly changing and evolving at a rapid rate.

The main focus of this entry will be *descriptive linguistics*, wherein linguists are concerned with understanding and describing how language *is*, a feat traditionally accomplished by field work, wherein linguists make a specific effort to document a language *in situ* in the culture where it is spoken. This can be contrasted with *prescriptive linguistics*, which proscribes how particular parts of a specific language *should* be. Having prescriptive rules in a language is necessary particularly for teaching and writing contexts, and very often, descriptive work on a particular language will eventually inform prescriptive rules that are taught to learners or writers.

However, the vast majority of linguists engage in descriptive work of some kind, and it is particularly this type of work that is usually more revelatory about human evolution and evolutionary psychology. If linguists approach the study of language with a prescriptive slant, they risk overlooking important and potentially revealing phenomena. This means that while we consider a

language to be a cohesive unit, at least conceptually, linguists not only acknowledge but are particularly interested in linguistic *variation* both within and across speakers.

This entry will start with an operational definition of what language *is*. Although humans use it almost constantly – and there is a sense that language is somehow different from other animal communication systems – there is a specific set of features which set language apart. After defining the object of study in more detail, the entry will delve into a more technical breakdown of how linguistics is studied.

Like other sciences such as biology, psychology, and physics, linguistics is fundamentally diverse and includes several subfields which illuminate different aspects of human language and cognition. After an introduction to the different facets of linguistics, the entry will conclude with a brief overview of the major ongoing debates and divisions in the field, many of which mirror larger issues being grappled with in other areas of cognitive and social science. Understanding these broad divisions the field is crucial to understanding how it interleaves and interacts with evolutionary psychology and cognitive science more generally.

What Is Language?

Human language is a complex phenomenon, a fact often lost given how easily children learn languages, and how effortlessly we use language day to day both for communication and thought. Although the question “what is language?” may seem at first glance to be a trivial one (it’s what you’re reading right now, it’s what we speak every day, etc.), a formal definition of language is more difficult than it seems. There are currently estimated to be between six and seven thousand different languages spoken on the planet, and they exhibit considerable variation (Dryer and Haspelmath 2011). In many respects, there is still debate about what language is, what language isn’t, and what it is for. This section will give an overview of a well-accepted operational definition of language and provide more detail about how language is organized and studied.

Design Features of Language

In 1960, the linguist Charles Hockett identified 13 design features of language. Originally, the first feature was that languages occur in the vocal-auditory channel; at the time, there was a paltry understanding of the richness of sign languages which use a gestural-visual channel, as well as little acknowledgment of the role of the gestural channel even in spoken languages (McNeill 2000; Tomasello 2009). Given this updated understanding, this feature is now often omitted. To be concise, this entry will generally refer to speech and hearing, but unless otherwise noted, anything that applies to a speech signal being sent/uttered or heard/received in a spoken language context also applies to a linguistic gesture being signed/uttered or seen/received in a sign language context. The remaining 12 features identified by Hockett (1960) have stood the test of time and provide a useful operational definition of language by delineating what language is (and is not) in terms of what it can do and how it does it.

Language has (i) *broadcast transmission with directional reception*, meaning that while a speech signal can be heard by anyone within auditory range, the speaker (i.e., the direction from which the utterance came) is readily identifiable. Language is also (ii) *rapid fading*, meaning that speech sounds can only be perceived as they are made and are by definition impermanent (a feature shared by many other animal communication systems).

Writing systems naturally change this dynamic by providing a visual analogue of spoken language which lasts much longer, potentially thousands of years. However, particularly in an evolutionary context, writing systems tend not to be a central focus, since they are young relative to spoken language. While the oldest writing systems are estimated to be perhaps 5–6,000 years old, human language itself is much older, with estimates ranging from at least 100,000 years old to millions of years. Nonetheless, written language interacts with spoken language where there is a written form (this will be further discussed in detail in the “[Tools and Methodologies](#)” section).

Language is also fundamentally (iii) *interchangeable* – that is, speakers and hearers can uniformly use the language in the same way.

This is a property not shared by many animal communication systems, which may exhibit cross-species communication where sender and receiver cannot articulate the same signals, or where conspecifics exhibit marked sex differences (e.g., in many bird species, males have complex songs, while females do not). Another feature of language is (iv) *feedback*, that is, a speaker can hear themselves and control and modify their own signal as they produce it. Linguistic signals are also (v) *intentional*, that is, they are intended consciously by the speaker to be communicative, unlike, for example, how a limp in a prey animal would unintentionally communicate weakness to a predator.

Language is simultaneously (vi) *semantic* and (vii) *arbitrary*. Language conveys specific meaning or *semanticity*, but the form of a linguistic signal has an arbitrary relationship with its meaning. In other words, while English speakers share a convention that the word *rose* represents a specific type of flower, there is nothing about the sounds in the word *rose* that point to that meaning beyond this shared convention – in other words, a rose, by any other name, would still smell as sweet. Although some words in language are non-arbitrary – for example, in an onomatopoeic word like *hiss* the sound of the word is similar to and representative of the sound a snake makes – the vast majority of linguistic symbols are arbitrary.

Language also exhibits (viii) *discreteness* and (ix) *duality of patterning* – language is discrete in that it is made up of distinct units which combine and recombine in rule governed ways. Duality of patterning means that these discrete units occur at two levels: individual sounds – which are themselves meaningless – form together to make meaningful units, which can in turn combine again to make meaningful utterances.

These properties contribute to another feature, (x) *productivity*. Productivity refers to the fact that the rule-governed recombination of meaningless and meaningful units gives rise to the ability for speakers to create and interpret novel utterances (this feature is sometimes also known as *generativity*). Duality of patterning – and thus, the level of productivity present in human language – is arguably unique to human language and has not been definitively shown in any other

animal communication system. However, relatively little is known about dolphin communication, and the possibility remains that it (or other understudied animal communication systems) exhibits one or both of these features to some extent.

Language also enables *displacement*, or the ability to talk about and refer to things that are not necessarily present, concrete, or even true. While other animal communication systems might have both arbitrariness and semanticity (e.g., macaque warning calls to signal the presence of different predators), which should in theory allow for displacement, in practice, this type of displaced reference is thought to be unique to human language. Although instances of deception have been documented in other primates, these are relatively rare (Whiten and Byrne 1900). Using language, we can talk about language itself (a property known as (xi) *reflexiveness*), and unlike many other forms of animal communication, language is not constrained to honesty: although one could easily exaggerate their personal athleticism using words, the signal an animal would use to display physical fitness is often the physical fitness itself, and so exaggeration is virtually impossible (see Zahavi and Zahavi 1990).

Finally, language is crucially (xii) *learnable* and (xiii) *culturally transmitted*. In order to persist over generations, language has to be both learnable and usable – for example, although binary code can be used to convey complex messages, and the use of only two minimal units

(1 and 0) is arguably highly efficient, children would have a very difficult time learning a rich expressive system in binary, and so language structure takes a very different form. It is also crucial that language learners acquire their language from other speakers, and other learners will in turn acquire from their production. Many researchers argue that many of the properties we observe in language are the result of biases in learners which are amplified by cultural transmission (Chater and Christiansen 2008).

Given these design features, it is generally accepted that no other known natural communication system can do what language does. While many animal communication systems may share some features with human language, no known system combines all of these features in the way that human language does.

Levels of Language

The current understanding of language generally divides its structure into six interacting areas (1): *phonetics*, *phonology*, *morphology*, *syntax*, *semantics*, and *pragmatics*. This section will aim to give a very brief overview of these areas and how they interact with one another. Starting with phonetics and moving up through semantics and pragmatics, these areas become increasingly broad: phonetics focuses on the fine-grained acoustics of language, while pragmatics focuses on whole linguistic interactions, including not just speech sounds, but inference, implication, and common ground (Fig. 1).

Field of Linguistics, The, Fig. 1 The levels of language, forming interacting areas of linguistic study. Areas become more broad from left to right: with phonetics involving

acoustic description well below the word level and pragmatics encompassing entire interactions (Definitions adapted from O’Grady et al. 1996)

Phonetics and Phonology

Phonetics and phonology both involve the sounds of language, but the distinction between the two areas is important. While phonetics studies speech sounds that humans can produce in language generally, phonology deals with the rule-governed, patterned organization of speech sounds in a particular language. Phonetics deals with the acoustic properties of human speech, while phonology deals with sound patterns in specific languages. As an illustration, while aspiration is a phonetic property which occurs in many languages, the phonology of aspiration is different in different languages (e.g., in English, *p* is aspirated depending on where it is in a word, whereas in Thai, *p* is aspirated depending on what the word means).

A description of a language's phonology will include an inventory of its *phonemes*, defined as the sounds in a language that are contrastive with respect to meaning. Although sign languages have no acoustic component, they do have what are considered to be phonologies, only the "phonemes" are visual features such as hand shape, position, and facial expression (Brentari 2011). Although the human vocal tract can make hundreds of distinctive sounds (and human hands can make hundreds of distinct gestures), individual languages use these available units as phonemes to varying extents – the language with the most phonemes is !Xũ (spoken in southern Africa, with 141 phonemes), while the language with the least is Rotokas (spoken in Papua New Guinea, with only 11 phonemes; Crystal 2010).

A language can make use of a particular sound, or *phone*, without it necessarily being classed as a phoneme. To return to the aspirated version, while both *p* and *p^h* occur in both English and Thai, these are only two separate phonemes in Thai, where the presence or absence of aspiration can change the meaning. On the other hand, one could aspirate the *p* in the English word *stop*, and it might sound strange or emphasized, but it wouldn't be a different word. This means that in English, *p* and *p^h* are *allophones*, defined as variants of a phoneme which change slightly depending on context.

In order to describe phonology with maximum accuracy, linguists employ the International

Phonetic Alphabet (IPA), which uses hundreds of symbols to describe the sounds found across human languages. This tool is crucial for an accurate description of a language's phonology – for example, the Roman alphabet has only 26 letters, but English itself has about 44 phonemes (slightly more or less depending on the variety of English being described). Beyond this, the IPA allows researchers to describe and compare the phonologies of disparate languages in a systematic way, such that direct comparisons can be made between genetically distant languages with different writing systems like English and Thai.

What sounds are relevant in a language is equally as important as how those sounds combine. The rules that govern sound combinations in a language are known as *phonotactics*. While a language might include, for example, 30 phonemes, these sounds are not generally combined in unrestricted ways. For example, while the sound *-ng* (the sound at the end of the word *interesting*, represented in the IPA as ŋ) occurs frequently in English, it never occurs at the beginnings of words. This may seem like a physical constraint to a native English speaker (i.e., they have difficulty pronouncing ŋ without a vowel before it), but this sound does occur word-initially in many of the world's languages, so this is simply a phonotactic quirk of English.

Morphology

While in phonology phonemes provide *contrasts* in meaning, by definition they do not *encode* meaning. That is, although *pat* and *bat* mean different things, and differ only in the sounds *p* and *b*, the sounds in and of themselves mean nothing. This changes at the level of *morphology*, where a *morpheme* is defined as the smallest unit of meaning in language. Phonology and morphology interact considerably: first, morphemes are necessarily governed by a language's phonological and phonotactic rules. Second, phonemes are the minimal units which comprise language and recombine to form the minimal *meaningful* units represented by morphemes – this property is often known as *combinatoriality*, which forms one of the two parts of the crucial duality of patterning identified by Hockett (1960).

Morphemes are often entire words, like *pat* and *bat*, known as *free morphemes*. Morphemes can also be bound, meaning that they contain semantic information, but only occur bound to other morphemes. For example, the morpheme *un-* contains meaning in that it can negate an adjective (e.g., *unbearable*, *uninviting*), but it cannot stand on its own as a word-unit – it must be attached to what is known as a *root* (in the previous example, *bearable* and *inviting*) via *affixation*.

Bound morphemes also come in two general types: *inflectional* and *derivational*. Inflectional morphemes alter meaning (un-like) but cannot change the category of a word (i.e., *bearable* and *unbearable* are both adjectives). Derivational morphemes, on the other hand, do alter category – for example, the bound morpheme *-able* transforms the verb *bear* into the adjective *bearable*, and can be similarly productively applied to make adjectival forms of other verbs (e.g., *share* → *shareable*).

While these examples all come from English for ease of understanding, these morphemic categories can be used to describe any language, although different languages use different morphological processes to different degrees. Languages can be classified according to their predominant morphological strategies along two main continua: the synthetic-analytic continuum and the fusional-agglutinative continuum. In *analytic* languages, most words are a single morpheme (i.e., bound morphemes are rare, and words tend to be uninflected). On the other hand, highly *synthetic* languages have single words which may contain many morphemes. Among languages with some degree of synthesis, inflection can be either predominantly *fusional* or *agglutinative*. In fusional languages, bound morphemes are indistinguishable from the roots to which they attach and may involve subtle changes in stress or tone. In agglutinative languages, bound morphemes are well delineated and readily identifiable and are generally attached to roots via affixation.

Syntax

Morphology interfaces to a large extent with *syntax*, roughly defined as the rules governing word

order in language. This interface is comprehensive enough that some research focuses specifically on the intersection between morphology and syntax, known as *morphosyntax*. The morphological properties exhibited by a language often give hints as to some syntactic properties of the language. For example, languages which are highly synthetic are more likely to have some flexibility in syntactic rules. Since in a synthetic language properties of a word's component parts provide grammatical information, word order is often varied or may be used to convey nongrammatical information. For example, in Italian, verb affixation encodes the subject (e.g., *io cammino* [I walk] vs. *tu cammini* [you walk]), such that speakers can simply say *cammino* and drop the subject all together, or invert the order (*cammino io*) to emphasize the subject. In English, on the other hand, subject drop is impossible. Without the subject pronoun, substantial semantic information is lost – the obligatory subject inclusion and fixed subject-verb order has too heavy of a functional load to be optional.

Beyond its interaction with morphology, syntax is a large independent field within linguistics. Although the roots of linguistics generally grow out of anthropology, the field underwent a formative shift in the late 1950s. This shift was spearheaded by the publication of Noam Chomsky's book *Syntactic Structures* (1957, 2002), which drew more heavily on mathematical formalisms than traditional descriptive field work. Chomsky's work focused on creating a *generative grammar* of a language given some minimal sample of it. In other words, he sought to formalize a minimal set of rules from which all valid utterances of a language could be generated.

This influential work had the effect of making an understanding of syntax central to an understanding of language, and thus, central to modern linguistics. Syntax is sometimes identified as the feature of language which makes it unique to humans (Hauser et al. 2002), and, coupled with morphosyntax, as the primary driver of linguistic productivity – the other half of duality of patterning (meaningful subparts coming together to form larger meaningful wholes). The syntactic structure

of language means that a finite set of rules can generate an infinite set of valid utterances, and generally underlies a form of hierarchical structure which makes language particularly productive: *recursion*.

Recursion is the process by which a particular type of phrase can include an instance of itself, meaning that it can build upon itself indefinitely. As a visual example, think of two mirrors facing each other, resulting in an image of mirrors inside of mirrors inside of mirrors, ad infinitum. In broad terms, recursion means that you can have sentences inside other sentences. This means that in theory, a single sentence could have infinite length (e.g., *John knows that [Mary knows that [I know that [David knows...]]]]*), although in practice memory and processing limitations generally place constraints on this. Some research has even tied this recursive ability to the ability to recursively represent the mental states of others (also known as *theory of mind*) (Corballis 2014), a cognitive ability that is relatively rare in the animal kingdom (Hauser et al. 2002). While there is considerable syntactic variation among the world's languages, most all languages make use of recursion, and where this hasn't been definitively shown (most notably in Pirahã; Everett 2013), all humans seem to have the *capacity* for recursion, a feature not definitively demonstrated even in unusually sophisticated language trained apes (Hess 2008).

Semantics

Although syntax is productive, and makes language well suited to conveying complex ideas and relations, language is also fundamentally defined by the fact that it can reference meaning (i.e., the semanticity identified by Hockett). Syntax is to some extent divorced from meaning, known in linguistics as *semantics*, and there are two main pieces of evidence for this.

First, there are animals whose communication systems exhibit many features of syntax, but the systems do not engage in referential meaning. For example, both birdsong and whale song have been found to have repeating elements and features of hierarchical structure (Cate and Okanoya 2012), but the meaning

these carry is broad and unchanging (something along the lines of, “mate with me”). Meaning in human language, however, is incredibly nuanced, expressive, and constantly changing, to the point where it can express entirely new ideas with ease. Although some rudimentary form of structure seems to exist in some animal communication without rich semantic reference, semantic productivity is fundamentally tied to syntactic and morphological processes. For example, morphological processes mean that in the space of a couple of decades speakers can go from barely having a shared concept of [SEARCH ENGINE], to having nouns (*google*), verbs (*to google*), and adjectives (*googleable*) growing out of this concept.

The second piece of evidence for a divide between syntax and semantics comes from human language itself. First, sentences can be syntactically well formed but semantically vacuous or nonsensical. Chomsky's famous example was the sentence “Colorless green ideas sleep furiously” (Chomsky 2002). In terms of a grammar, this sentence is perfectly well formed, but semantically, the sentence is at best nonsense and at worst downright confusing. Second, brain damage as a result of stroke or injury can selectively effect syntactic or semantic processing. Language disorders known as *aphasias* (from the Greek *a-* “without” and *phasis* “speech”) can be divided into Broca's aphasia, which seems to predominantly effect sequential processing (resulting in halted speech), and Wernicke's aphasia, wherein patients display speech often syntactically fluid but deficient in terms of content words (e.g., nouns, verbs) (Harley 2013).

As with the other levels of language, languages vary semantically, although this is generally less straightforward to quantify than phonological, morphological, or syntactic variation. Researchers can take text from a language and make very good inferences about its general syntactic structure with little semantic information, but gathering detailed semantic information requires considerable effort and, ideally, access to native speakers. Broadly, semantics is studied in from a variety of perspectives, with approaches ranging from formal logic with a

root in philosophy to approaches from psychology which consider meaning from a more cognitive perspective. Prior to Chomsky's syntactic revolution, two prominent figures in linguistics, Edward Sapir and Benjamin Whorf, went so far as to suggest that linguistic meaning could in fact shape cognition itself, arguing that the language one speaks can constrain thought. For example, while a language like English makes a distinction between the concepts of *on* and *in*, a language like Korean does not (using a single word to express both). Sapir and Whorf argued that this kind of difference could have meaningful consequences in terms of cognition. Although a strong version of this hypothesis (known as *linguistic determinism*) is now generally rejected, there is some evidence for an interplay between concepts in language and concepts in cognition (Everett 2013).

Pragmatics

Semantics deals with meaning which is encoded within linguistic signals themselves; roughly, how we know that the sequence of sounds in *rose* generally means a particular type of flower. Pragmatics, on the other hand, deals with meaning that is not necessarily conventionally encoded in the linguistic signal itself, but arises from communicative context and common ground. Communicative context is roughly defined as the context in which an utterance is made, for example, while the (spoken) utterance "that's my rose" is a perfectly well formed sentence both syntactically and semantically, what it actually means is highly *ambiguous* out of context. What "that" refers to and what is intended by ROSE (an actual flower, a ceiling rose, a person named Rose, etc.) is impossible to resolve without access to the communicative context. *Common ground* is a specific kind of context that comes from having a history of interactions (e.g., between close friends) or shared group status: for example, if a hearer was already aware that the speaker knew someone named Rose, it would resolve much of the ambiguity in the utterance "that's my rose".

Pragmatics can be challenging to study, since it is in essence the study of how we say things

without ever actually *saying* them – for example, it is trivial for someone to understand the declaration "I'm cold" to actually *mean* "close the window," even though the speaker never said anything about windows or closing. Studies in pragmatics aim to illuminate how context resolves ambiguities and potentially even imbues meaning barely hinted at in the linguistic signal itself, how common ground is built, and the rules that govern linguistic *interactions* (as opposed to linguistic *signals*). Pragmatic rules vary greatly from culture to culture, as well as between subcultures and contexts. For example, in the context of press conferences surrounding North Korean nuclear negotiations, American officials were more likely to offer outright refusals to answer a question, while Chinese officials were more likely to avoid a question or provide a circumspect answer (Jiang 2006). Outside this context, avoidance might be interpreted as a genuine lack of knowledge, but contextualized in a culture where this strategy is commonplace, avoidance pragmatically communicates a desire not to answer the question, without being aggressive or threatening to the questioner.

Pragmatics necessarily interfaces with sociology, anthropology, and psychology in specific ways while also interacting heavily with all other levels of language. Theory of mind and mind reading are central to pragmatics: without the ability to hypothesize about the internal states of others, it becomes difficult to imagine how we would draw meaning from context or common ground, particularly where *most* of the meaning is drawn from these factors (e.g., as with using "I'm cold" to actually mean "close the window"). In terms of other levels of language, pragmatic considerations can govern variation at the phonological, morphological, and syntactic level. For example, a phonetic phenomenon known as "g-dropping," wherein a speaker says "goin" or "drawin" (in lieu of "going" or "drawing") is often conditioned by context, such that it is more likely in informal contexts (Labov 2001). Likewise, word choice (e.g., "died" vs. "passed away") or sentence structure is often pragmatically conditioned, even within a single speaker.

Tools, Methodologies, and Subfields

Tools and Methodologies

Language is most usually studied at least partially through the lens of the areas of linguistics identified above, but how this study is approached can vary greatly. Methodologically, approaches to the study of language usually fall into one of three categories: naturalistic data, experiments, and computational models.

A linguistic corpus (plural *corpora* from the Latin for “body”) is a body of text which can be used as data to study language. Corpora can be used to study phenomena at almost every level of language – there are even pragmatically annotated corpora – and they have become increasingly essential in linguistic research in the last few decades. While text sources have long provided a useful source of data for linguists, until relatively recently, their reach was necessarily limited. Corpora were generally small and not randomly sampled – for example, a collection of published fiction can reveal a lot about style in fiction and popular themes, but it does not provide a good representative sample of a language.

In the advent of the Internet age, corpora have become much more widely available as well as more comprehensive – the freely available Google Books corpus covers over 150 billion word tokens in English and also has (usually slightly smaller) corpora in several other written languages (Linell 2004). This means that linguists have been able to gain new insights into many properties of language, such as linguistic change occurring over hundreds of years (Cuskley et al. 2014) and language varieties diverging as they disperse across the globe (Michel et al. 2011). Likewise, other fields such as complex systems science and physics have begun to overlap and interact with linguistics due to the ready availability of a great deal of linguistic data which can shed light on dynamic social and cultural dynamics more generally.

While there are available corpora of spoken natural language, such as the CHILDES Corpus of child language (MacWhinney 2000) and the Switchboard Corpus (Godfrey and Holliman 1993), available language corpora are

overwhelmingly drawn from written language. Due to its permanence, written language provides a rich source of data for linguists to study, but caution is required when it comes to general conclusions drawn from most corpora. First, while written language is a mirror of its spoken counterpart to some extent, some results gleaned entirely from written corpora might only apply to written language.

More problematically, many general conclusions drawn about language are heavily skewed towards languages which have a written form, meaning interesting features which may occur in languages which are exclusively spoken are overlooked or difficult to even discover in the first place. This forms part of a general bias towards making assumptions and conclusions about human language generally from a relatively confined and homogenous set of European languages (Linell 2004). Even where spoken corpora are used, these are overwhelmingly drawn from languages which have a written form. Thus, there is still a very important place in linguistics for traditional fieldwork, particularly to gain knowledge about languages spoken by smaller populations which may not have written forms.

Experimental approaches in linguistics are relatively new to the field – before the latter half of the twentieth century approaches were predominantly anthropological or theoretical. The experimental methodologies used in linguistics are often borrowed from experimental psychology. Common experiments with high relevance for linguistics are Artificial Language Learning (ALL) experiments, lexical decision experiments, and grammaticality judgments.

In ALL experiments, participants learn miniature artificial languages. How quickly and accurately they learn these languages, and what kinds of errors they make in learning, are often revealing about how we process language. Lexical decision tasks involve participants making split-second decisions about words, often about their meaning in a categorical sense (e.g., is the word “spaghetti” a noun or a verb). These experiments can reveal a lot about how the levels of language interact in processing, for example, semantic information might interfere with making syntactic category

judgments (such that “destruction” would be more difficult to identify as a noun than “spaghetti”). Grammaticality judgments involve asking participants to rate the acceptability of different sentences, in order to allow for a comprehensive description of the generative rules which govern a language. Aggregate grammaticality judgments over many participants allow researchers to describe in greater detail the rules that underlie, for example, why *the girl rode the bike* is acceptable, but **the girl looked the bike* is not.

Various other experimental methods are employed in linguistics, and many of them are combined with other experimental approaches, such as having a participant complete a lexical decision task inside an fMRI machine to better understand how language processing works in the brain. However, as with corpus linguistics, some caution is warranted given the fact that participants in studies are not only overwhelmingly Western, literate, and often specifically European but, like in psychology generally, tend to be a specific subset of this already confined sample (often university undergraduates; Henrich et al. 2010).

Computational models are also an invaluable resource in linguistics. Although there is a necessary level of abstraction in computational modeling, the approach also allows for considerable control, and in many cases a view of language processing and/or transmission which is not language specific. At the individual level, computational modeling allows for insights into how we process language. For example, by trying to teach a simple network to accurately learn the English past-tense given minimal input data, we can gain insights into how our own brains might solve this problem (Pinker and Ullman 2002). Computational models also offer the opportunity to examine large-scale population level phenomena by using populations of artificial agents. This allows for crucial insights into how language is used across large groups and transmitted between learners, providing a valuable complementary resource to the smaller-scale data provided by experimental approaches.

Computational approaches are essential for more practical applications in linguistics, such as machine translation and advances in artificial

intelligence. However, despite considerable progress in both of these areas in recent decades, artificial intelligence is far from having comprehensive linguistic competence. In terms of machine translation, while there is unprecedented accuracy at the level of individual words, the error rate in automatic translation of longer texts is considerable, and this is to say nothing of machines interpreting much noisier natural speech. While the ability to do this has improved considerably in recent decades, there is still a noticeable level of error particularly with different language varieties (e.g., many speech recognition systems do not handle non-standard accents well). The area where a failure of AI to meet human performance is most noticeable is arguably in pragmatics. Although an AI might be able to interpret and answer a single question (e.g., like Apple’s Siri © or Amazon’s Alexa ©), and produce fairly realistic-sounding speech, realistic sustained conversation is an open problem. While there is clearly room for improvement in all of these areas, more advances have been made in the last decade than in the previous century.

While naturalistic data, experiments, and computational approaches arguably form the methodological core of linguistics, other approaches provide valuable contributions to the field, which, like any other field, is constantly changing and growing. Comparative approaches which aim to describe the communication systems of other species can provide valuable insights into human language, especially attempts to teach language-like systems to nonhuman animals. Formal mathematical approaches have been revolutionary in syntax, and information theory and complex systems science have made promising inroads into formalizing broad properties of language.

Conclusions

The previous sections provided a concrete operational definition of what language is, identified the different levels at which it is structured, and briefly outlined how the study of language is approached methodologically. While basic facts about language are broadly agreed upon in the

field, there are of course divisions within the field and open questions. Researchers in the Chomskian tradition are proponents of *Universal Grammar* (UG), which proposes that some minimal aspects of language are innately (or even genetically) encoded. However, many functional or cognitive linguists argue that learning plays a crucial role not just in the individual development of language but in shaping the structure of language itself over time (Chater and Christiansen 2008). Very broadly, this debate mirrors the “nature-nurture” question at the heart of many problems in cognitive science.

A related open question concerns the *domain specificity* of language. Proponents of UG lean towards the notion that the processes involved in language are specific to language and specifically evolved for language. On the other hand, cognitive or functional linguists argue that more *domain general* constraints – such as memory or a general preference for simplicity over unnecessary complexity – govern and shape language.

Nonetheless, researchers broadly agree that language is defined by some essential features, the particular combination of which makes language unique among other communication systems. Particularly, the discreteness, duality of patterning, arbitrariness, and productivity of language allow it to engage in displacement. This means that unlike many other communication systems, language is theoretically an infinite system (particularly due to recursion) and can be readily used to engage in communicating things that are neither present nor true. Language is formally divided into minimal meaningful units (phonemes), which combine to create minimally meaningful units (morphemes), which in turn recombine in syntactically rule-governed ways to create an endless array of meaningful utterances. The areas of phonology, morphology, and syntax study these properties in different languages, while the areas of semantics and pragmatics concern how meaning is encoded both within linguistic signals and in linguistic interactions. There are many ways to approach the study of language, but most often any given approach can be categorized as either leveraging naturalistic (often corpus-based) data, using controlled experiments, or targeted computational modeling.

Fieldwork

Definition

Gathering information by observing individuals in their natural setting.

Introduction

Field research (“fieldwork”) refers to information gathered by observing individuals in their natural setting. Field research can be both qualitative and quantitative in nature. Qualitative research emphasizes the importance of observing variables and their interactions. Quantitative research attempts to objectively gather data to make associations, comparisons, and predictions among variables. Field studies that sought to associate behavior with inter-individual interactions and/or the environment formed the foundation for the field of behavioral ecology (Martin and Bateson 2007).

Field research involves observations of free-living wild animals in their natural habitats while minimizing perturbations or disturbances to their environment or behavior. Field excursions may require some or all of the following (Lagler 1956): funding for travel, salary, supplies, and lodging; field assistants to help with data collection; information about the area; planning and coordination; and a schedule of tasks to be completed. Fieldwork may involve the observation, capture, and measurement of animals and collection of environmental data. Documenting the environment of the population under study is an interdisciplinary effort that may require knowledge of surveying, geology, chemistry, and botany.

Field studies can provide insight into the causes and complexities of animal behavior. Animals regularly interact with their environment through activities associated with breeding, eating, and movement. More accurate information may be obtained about these behaviors if they are studied in wild versus captive animals because captive individuals are often too constrained by artificial environments to behave naturally. Furthermore, evidence that a variable can influence behavior under laboratory conditions does not

mean that it influences behavior of wild animals. Field studies, therefore, are invaluable for observing the full range of an animal's behavior and understanding its ecological context. Observers are able to note the circumstances in which behaviors do and do not occur, which allow them to infer their function and proximate causes (Martin and Bateson 2007).

Exploratory data obtained from field observations can form the basis for follow-up experimental studies in artificial settings that can experimentally test for causality. Field studies aid understanding of how a behavior is adapted to a particular environment. Habitat can influence behavior, so it may be important to choose study sites that are in different environments to be able to generalize a species' typical behavior (Martin and Bateson 2007). Scientists can conduct controlled field experiments, in which certain aspects of the environment are manipulated to test a hypothesis. For example, to test weaverbirds' abilities to differentiate between their own eggs and those of other parents, researchers planted nests with the eggs of other parents (Lahti and Lahti 2002). By experimentally

manipulating gull eggshells, Tinbergen (1962) learned that parents remove broken eggshells to reduce predation by crows.

Goals of Field Sampling

Field studies can help scientists understand how individuals or species interact within populations or ecosystems, anthropogenic effects on individuals or populations, and a population's life history characteristics. Knowing the natural history and ecological context of organisms is also helpful in conservation efforts. Studies can focus on the distributions of populations/species, the presence/absence of a species in a given area (particularly a species that is threatened or invasive), determination of environmental limitations or advantages for a population, or obtaining specimens for further study in the lab.

Four main aspects of behavioral ecology can be addressed in field studies: action patterns, abundance, survivorship, and resource allocation (Bart et al. 1998; Table 1). When sampling

Field Research, Table 1 Types of field observations, goals, sampling methods, and potential difficulties (Bart et al. 1998)

Type of observation	Goal	Methods	Difficulties
Behavior	Estimate time spent engaged in different behaviors	1. Scan sampling 2. Focal sampling	1. Observer influences behavior 2. Animals disappear out of sight
Abundance	Estimate trends in population size in time or space	Surveys	1. Changes in survey efficiency can influence estimates 2. Defining the trend in population size 3. Missing data 4. Variation in observer skill 5. Pseudoreplication
Survivorship	Estimate the number of individuals that survive in a given time period	1. Telemetry 2. Nesting success 3. Capture–recapture	1. Finding and following all nesting attempts 2. Monitoring efforts unevenly distributed over time
Resource selection	Determine why animals use some areas or consume some food items while not using or consuming others	1. Surveys of habitat use 2. Behavior sampling	Modeling complexity

behavior in the field, the first step is to define the behavior(s) of interest and then estimate how often they occur. Activity budgets can be quantified by recording the proportion of time spent engaging in a behavior, its frequency, or average duration. The definitions of behaviors of interest, often outlined in ethograms, need to be specific enough for different observers to be able to interpret them in the same way. Depending on the behavior, activities may be divided into bouts, or periods in which a behavior is engaged in frequently.

When monitoring abundance, observers can estimate population size through time and/or space, often with regard to an ecological variable of interest. Population sizes may be estimated through the use of long-term surveys or telemetry. Field surveys can also lend insight into a population's resource selection, the process by which animals use a specific area or consume certain food items, while not using or consuming others. Additional characteristics of a focal individual may also be recorded (Table 2).

Field notes typically contain detailed descriptions of the physical environment and individuals under study, including their behavior and communication with others. Methodological notes describe how data are acquired as well as justification of techniques used and may incorporate ideas for future studies.

Sampling Methods

An observer might engage in either focal individual or scan sampling (Lehner 1996). Focal sampling follows only one or a few individuals, while scan sampling involves periodic observations of all or a subset of individuals in a group. Observers may sample either continuously or intermittently. In continuous sampling, the start and end times or occurrences of behaviors are recorded during finite time intervals. Intermittent sampling provides snapshots of an animal's behavior by recording their activity at regular intervals. Continuous sampling is best when

Field Research, Table 2 A description of an individual in the wild may include any or all of the following characteristics (Lagler 1956)

Category	Characteristics
Taxonomy	Genus and species
Range	Where is the organism found? How do the current and original ranges vary? What ecological factors influence the size of the range?
Distribution	What ecological factors influence distribution?
Physical description	Morphology Color Sexual dimorphisms
Foraging strategies	How do they change throughout development? How selective is the individual in choosing food? Does diet vary seasonally? What are the daily food requirements? How often does the organism eat? How do they eat? What factors influence what food is eaten and when?
Growth rate	What is the organism's age, length, and weight? Does the organism exhibit allometric growth? What factors influence growth?
Reproduction	When is sexual maturity? What is the sex ratio? Are there courtship rituals? When and how do individuals breed? How fertile are individuals? Do they exhibit parental care? What is the offspring's survival rate? Are the breeders oviparous or semelparous? What factors influence reproductive success?
Early development	What are critical environmental windows? When does hatching occur? How long is larval development? What factors influence development?
Behavior	What movements are observed? Does the species migrate? Do individuals school? Are they territorial? Do you observe individuals learning? Are individuals engaging in social behaviors? What factors influence behavior?

Field Research, Table 3 When reporting the results of field studies, the following characteristics should be included as appropriate (Lagler 1956)

Basic background	Location
	Nearby geographical features
	Map, including source and cardinal directions
	Coordinates
	Natural history
	Extent of development
Physical characteristics	Size of field site
Geological characteristics	Soil type
	Ground cover
	Vegetation type
	Presence of dispersal corridors
Chemical characteristics	Temperature
	Oxygen availability
	Salinity
	pH
	Extent of pollution
Biological characteristics	Food sources
	Predators
	Competitors

only a few easily recognized behaviors are recorded that either occur infrequently or last a long time while. Intermittent sampling is preferred for recording fine-scale behaviors that may change rapidly. Decisions about the use of one technique over the other requires an evaluation of the pros and cons of obtaining a lot of data on a few focal individuals or limited data on a larger number (Cochran 1977). Intermittent and continuous observations are commonly combined with general observations of group dynamics (Bart et al. 1998). Basic information about the individual or population’s environment should also be reported (Table 3).

One or a combination of sampling techniques may be employed (Bart et al. 1998). Simple random sampling refers to a situation in which all possible samples from the population are equally likely to be selected. Random sampling is not always feasible in natural settings, so nonrandom sampling may instead be used, particularly with regard to selection of focal animals. Researchers may choose to focus on individuals at a particular

developmental stage or focal individuals distributed evenly across a population.

Sources of Error

Both observer influences on behavior and measurement bias are potential sources of error in field studies (Bart et al. 1998). It is not uncommon for animals to change their behavior in the presence of an observer, and the extent to which animals are affected may depend on species and/or life stage (Martin and Bateson 2007). Therefore, an acclimation or acceptance period may be required if the animal appears to react to the researcher. Acclimation periods are typically short but vary depending upon the species being studied. The presence of an observer can also influence the behavior of the focal species’ predators or prey. As a result, it is important for the observer to minimize disturbances and wait until after the acclimation period to collect data.

Hides or blinds may reduce disruption, but can restrict the observer’s ability to monitor individuals. An animal moving out of sight can result in selection bias, when data are not recorded at the scheduled time, or measurement bias, if the individual is hidden for only part of the scheduled observation time. While the use of a hide or blind reduces the ability of animals to see the observer, it does not prevent the animals from detecting the observer’s sounds or smells. To further minimize the likelihood of disrupting normal behavior, remote video cameras may be used. While they may not be able to observe all of the behaviors of the individuals under study, resulting in selection and/or measurement bias, they create a permanent record of the behavior that can be replayed and may also help detect behaviors that occur so rapidly that they are difficult to record accurately in real time (Martin and Bateson 2007). An additional benefit of having a permanent record of behavior is that follow-up studies may be conducted without having to return to the field site. Recorded behaviors may also be used as educational tools

or deposited into open-access databases that are used by the research community.

Prominent Field Researchers

In the mid-1800s, Charles Darwin developed his theory of evolution by natural selection after conducting field observations of a variety of species while voyaging on his ship, the *Beagle*, and studying the plants and animals that were local to his home in England (Darwin 1859). In the 1920s–1930s, Margaret Morse Nice captured and marked sparrows in her yard and studied them throughout their development (Nice 1937). In the 1930s–1950s, Konrad Lorenz, Karl Frisch, and Nikolas Tinbergen developed the field of ethology, or the science of animal behavior. Their studies of numerous animal taxa, including birds, fish, and insects, helped researchers to better understand the causes of behavior, its evolution, and how it relates to fitness (Dewsbury 2003). At about this same time, J.H. Crook and David Lack used their studies of birds to develop a comparative approach to behavioral ecology in which they associated behaviors with the birds' environments (Lack 1947; Crook 1964). Jane Goodall began working with chimpanzees in Tanzania in the 1960s (Goodall 1990). Through her decades of field observations, she greatly increased our understanding of primate behavior and documented behaviors that were previously thought to be unique to humans, including tool use and warfare. Her work has helped protect wild primates and has publicized issues of animal conservation.

Definition

Neuro-cognitive processes involved in estimating others' and one's own ability to inflict harm and

other fitness-related costs in physical confrontation based on available cues related to the likelihood of success in physical conflict.

Introduction

When organisms are competing for the same resource there are multiple strategies that each individual might take. They might cooperate, they might try to scramble to outcompete, they might leave and seek alternative sources, or they might aggressively compete (Duntley 2005). This last choice is a decision to inflict costs on the other and is likely made where at least one of the other strategies are available. It is therefore an interesting question to analyse when and how organisms decide to aggressively compete.

While a number of factors will be at play in the wider context, such as the value of the resource and how divisible it is, for our purposes here we focus on the relative fighting abilities of the prospective combatants in a human context or as Parker (1974) describes it the decision whether to fight or not may be based upon an assessment of “relative resource holding potential.”

It is possible that assessment of the other prospective candidate may be unnecessary. Arnott and Elwood (2009) report that in a variety of species, there is evidence for a pure self-assessment where the prospective combatant pays attention to its own resources and health and will only deescalate from a fight if these resources drop below some trigger point. This strategy avoids the costly effort of evaluating others. There is some evidence for use of this reduced cost strategy in humans. Taller men (Watkins et al. 2010a) or merely individuals that feel powerful in the moment (Watkins and Jones 2012; Watkins et al. 2010b) have a reduced ability to discriminate differences in male facial dominance. This suggests that their self-assessment is sufficient to at least ignore rival characteristics although not precisely evidence that self-assessment would be enough to escalate to a fight.

What is more likely, however, is that human competitors mutually assess rivals before

considering escalating to physical aggression. Various models exist to describe this but all involves initial low-cost sampling of the rival abilities before escalating (Arnott and Elwood 2009).

In many species, agonistic conflicts with conspecifics are key determinants of access to fitness contributors like resources, territory, and mating opportunities or promotion in social hierarchy (Ellis 1995). Species that engage frequently in physical confrontations with conspecifics calibrate their behavior according to their relative fighting ability. Many such species assess fighting ability from visual, auditory, or olfactory cues. Moreover, individuals remember these assessments over time, use them to determine relative fighting ability, calibrate their assessments based on previous victories or losses in fights, and engage in ritualized behavior involving displays and mutual assessments of formidability, and these contests are frequently resolved when one of the antagonists surrenders, which prevents actual costly fights (Sell et al. 2012).

Any individual that can reliably assess the chance to win a conflict in advance and that can make more sensible decisions about whether to initiate, escalate, or retreat from a potential fight is likely to obtain selective advantage. Thus, it seems likely that natural selection would have favored the evolution of cognitive and behavioral mechanisms that would facilitate assessment of fighting ability and that promote the most appropriate decisions and responses to decrease costs and increase benefits from potential confrontations.

Perception of numerous socially relevant characteristics that are important in social contexts (e.g., confrontations and negotiations) are frequently determined by physical traits like conspecifics' morphology. In many species, direct visual inspection of others' physical size is well documented (Arnott and Elwood 2009) as primary determinant of social dominance and formidability (see Třebický and Havlíček 2017). Individuals across various taxa can recognize the relative dominance, including fighting ability, of their conspecific upon first encounter depending on displays of body size or presence and size of

armaments, ranging from paper wasps (Tibbetts and Lindsay 2008), hermit crabs (Neil 1985), monitor lizards (Frýdlová et al. 2017), numerous avian species (Fretwell 1969; Senar and Camerino 1998), domestic pigs (Rushen 1987) to non-human primates (Bergman et al. 2009; Ghazanfar and Santos 2004).

Recalibrational Theory of Anger

Fighting ability could be described as an ability to efficiently use physical strengths (among other means), against a conspecific antagonist. Greater fighting ability of the given individual should increase the costs the individual is able to inflict upon the opponent. The willingness to use ones' fighting ability against competitors is commonly mediated via anger. Individuals are deemed to use anger to convince others to treat them better, and the more power they had to harm others, the more convincing they would have been (Price et al. 2012).

The recalibrational theory of anger (Sell 2011) is a computational evolutionary model which proposes that the function of anger is to recalibrate individuals who place insufficient weight on the welfare of the angry individual when making fight-or-flight decisions. According to this theory, (i) individuals differ in terms of their anger thresholds and selective usage of negotiation tactics, (ii) they need to estimate others' traits relevant to the ability to inflict any costs (e.g., fighting ability) and provide any benefits (e.g., mate value or resource gathering potential), (iii) and use these estimates to calibrate their welfare trade-off ratios (Tooby et al. 2008). More weight is placed on the welfare of individuals who have higher Resource Holding Power – the abilities and willingness to inflict higher costs or appropriate benefits from others (Parker 1974; Sell 2011). Individuals with higher resource holding power easily win conflicts, attain preferential access to mates, and benefit themselves at the expense of others in other ways (Sell 2017). Individuals are expected to have evolved to calibrate their welfare trade-off ratios to maximize their own welfare. Such recalibration strategy confers important selective advantage over fighting without prior assessment.

Due to the significant role of mate selection in evolutionary theorizing, the vast majority of investigations in current behavioral sciences emphasize that intersexual selection (i.e., processes underlying mate choice) is responsible for men's phenotype (but see Sell et al. 2017; for review Třebický et al. 2012). However, recent studies suggest that a variety of masculine traits appears to be primarily designed for intra-sexual competition rather than for attraction of potential mates (Hill et al. 2013; Puts 2010; Sell et al. 2017).

Human inclinations towards antagonistic interactions have been displayed throughout our evolutionary history. Forensic evidence suggests that antagonistic interactions among our ancestors – especially among men – have been rather common and significant selection force in our ancestral environment (Manson et al. 1991; Walker 1997, 2001). Facial skeletal trauma supposedly caused by fist fighting exists in the fossil record of *Australopithecus* (Roper 1969) and early *Homo* (Wu et al. 2011) and many other samples of historic skeletal remains (Walker 1997). Historical records and ethnography literature contain numerous examples that acts of physical encounters are not exceptional in many human cultures across the globe (Archer 2009; Horns et al. 2015; Walker 2001) and ritualized combats in the form of folk wrestling and martial arts are also common and have a long history (Green 2010). As in many other vertebrate species, men show higher levels of physical aggression, engage in physical contests and homicides to members of the same sex more frequently than women, and since practically all wars were fought prevailingly by men, this potential seems to be much higher among men than women in virtually all societies worldwide (Archer 2004, 2009). These patterns suggest a relatively high level of male intrasexual physical competition in human evolutionary history. This may account for some typical features of the human male physique, especially for the upper body shape and a greater amount of muscle mass and strength compared to the female body (Lassek and Gaulin 2009). Evolutionary-informed scholars therefore argue that physical encounters have probably

generated powerful selection pressures in humans as well that have contributed to the establishment of various neurocognitive and behavioral complexes, whose function is to perceive, assess, and specifically act in antagonist situations or even prior to actual encounters (Carré et al. 2013; Puts 2010; Sell et al. 2009a).

Physical Armaments

Physical competition often favors evolution of anatomical armaments (structures used as weapons or armors). Unlike some other animals, humans are not equipped with dangerous weaponries such as sharp canines, claws, or poisonous glands. Before humans started using and fabricating objects as weapons, physical combat had depended on hits executed by hands and striking with fists appears to be universally employed in many cultures across the globe as dominant striking technique used in modern combatant arts and “street fights” as well (Horns et al. 2015; Morgan and Carrier 2013; Scoggin et al. 2010). Ancestrally, a man's upper body strength was therefore a major component of his ability to inflict costs on others. Upper-body strength is considered as critical for physical encounters, particularly for wrestling, punching, or choking, which were the most common types of combats in ancestral populations according to analyses of skeletal remains (Walker 1997). Hence, greater strength should set the individual's formidability higher.

Interestingly, hand morphology which is similar to modern humans was present in basal hominins (Horns et al. 2015) and although, proportions of the hand may improve manual dexterity, at the same time they make it possible for the hand to clench into fist and be used as a club against opponents. According to the protective buttressing hypothesis, bones of the human hand are proportioned in a way so that they provide a supportive buttress while clenched into fist which protects the hand from injuries and also that the human fist functions effectively to strengthen and stabilize the hand during punches, which allows competing males to strike with higher force while substantively reducing the risk of hand injury (Horns et al. 2015; Morgan and Carrier 2013). Nevertheless, the frequency of

hand bone fractures resulting from fighting (Jeanmonod et al. 2011) has been used to argue that the hand is too fragile as a weapon (King 2013). Importantly, in fist fights the primary target is the face (Brink et al. 1998), and bones of our faces break much more frequently than do bones of the hands during fights, indicating that the fist is a sufficiently effective weapon (Carrier and Morgan 2014).

Facial Morphology

Studies focusing on the locations of injuries that result from assaults and interpersonal violence found that the face was the most common site (Brink et al. 1998; Shepherd et al. 1990) and fractures most frequently occurred in the mandibles, nasal complex, zygoma arches, maxillae, and supraorbital arches. Interestingly, the bone structures that suffer from the highest fracture rates are the parts of the skull that exhibit the greatest increase in robusticity during the evolution of genus *Homo* (Carrier and Morgan 2014) and are the most sexually dimorphic parts of the human skull (Enlow et al. 1996). Overall facial shape, expansion, and bunodont form of post canine teeth, increased robusticity of the orbits, excessively stronger masticatory system are the traits that tentatively represent functional features of protective buttressing of the face against injury during fighting (Carrier and Morgan 2014). It is also likely that masculine features of the face convey direct information about the degree to which the face is vulnerable to injury. A robust facial skeleton may make an individual stronger opponent simply because he is less susceptible to knockouts and serious injury.

Understanding others can help one to forecast others' future behavior and adjust oneself accordingly. Being able to assess mating interests, trustworthiness, willingness to cooperate, or formidability of conspecifics is of high importance for individuals' fitness, therefore to have neuro-cognitive mechanisms that work for perceiving and responding to these characteristics and intentions would be very effective. Such mechanisms should swiftly recognize adequate cues in others relying minimally on direct interaction and should be sensitive to cues that are related to fighting

ability in this instance. This is carried out by first impressions – impressions that can be formed very quickly, based on whatever information is available. Such first impressions are often formed by using, among other features, the visual appearance of physical features of one's face. A substantial body of evidence shows that people attribute various characteristics to others based on their facial appearances like physical strength (Holzleitner and Perrett 2016; Sell et al. 2009a) and aggressive behavior (Carré et al. 2009), among others.

Converging lines of evidence show that people infer various psychological traits based on static facial features. For instance, people judged as more powerful were reported being higher in assertiveness, aggressiveness, and power (Berry 1991), those who were judged as stronger and better fighters were physically stronger (Sell et al. 2009b), fighting success was congruently assessed (Little et al. 2015; Třebický et al. 2013, 2015), and even criminals who were judged as more violent were more likely to have been confined for violent crimes (Stillman et al. 2010). Majority of research on cues of threat potential in humans has investigated the relationships between measures of men's threat potential such as body size, upper-body strength, or actual fighting ability and assessments of their facial traits (Arnott 2017; Sell 2017; Sell et al. 2012; Třebický et al. 2013). Several studies have reported positive correlations between measures of men's upper-body strength and ratings of their facial dominance, strength, and ascribed fighting ability (Fink et al. 2007; Holzleitner and Perrett 2016; Windhager et al. 2011). Other studies found that faces of taller men are perceived as more dominant (Burton and Rule 2013; Re et al. 2013a; Watkins et al. 2010a). Ratings from distinct cultures including hunter-horticulturalists, people from industrialized regions, and pastoralists show that cues of physical strength and aggression are present in the face and that these cues can be extracted and assessed rapidly and accurately (Sell et al. 2010; Short et al. 2012; Třebický et al. 2015; Zilioli et al. 2014). A recent study by Han et al. (2017) showed that men's perceived "facial threat potential"

(a composite measure derived from dominance, strength, and weight ratings based on their faces) was positively related to their scores on the “actual threat potential” (constructed from men’s handgrip strength, weight, and height). Man’s handgrip strength (a proxy measure of upper body strength) is positively correlated with women’s ratings of their facial dominance (controlling for age and body weight) (Fink et al. 2007). Also, perceived strength from faces is correlated with actual muscle performance (Holzleitner and Perrett 2016; Hugill et al. 2009) and peer ratings of each other’s fighting ability are tracked by rating of dominance from facial images by strangers (Doll et al. 2014).

Threat Potential May Not Directly Relate to Formidability

It should be stressed, however, that previous studies concerning assessment and measures of formidability (Han et al. 2017; Sell et al. 2009b) rely on body strength or body size as a proxy for fighting ability. While physical strength is undoubtedly an important component of fighting ability, there are many additional sources of variation in the ability to fight. These studies are rather studying a threat potential; however, even high threat potential does not need to translate into actual fighting ability. Several researchers (Dixson et al. 2017; Kraus and Chen 2013; Little et al. 2015; Palmer-Hague et al. 2015; Pollet et al. 2013; Třebický et al. 2013) have overcome this issue by using available data on fighting ability from databases of mixed martial arts contests. Nevertheless, the generalization from these data might be limited as the sample consists of elite athletes highly skilled in hand-to-hand combat and individual bouts are fought only within restricted weight classes.

In most cases of hand-to-hand confrontation in general public, little-to-no experience or formal training can be expected, and therefore other factors like overall body size that influence the outcome of a physical fight must be at play. The fighting ability is undoubtedly a complex skill affected by various characteristics (i.e., ability to concentrate in stress, hand-to-eye coordination, overall stamina, or experiences) and our

knowledge in this area is far from definite and contribution of other characteristics may vary according to the form of the fight.

A growing body of research aims to identify exact facial (and bodily) morphological traits and whether people use them as visual cues to estimate those characteristics from the face and body and subsequently test how accurately perceived characteristics relate to relevant morphological structures. For example, in the case of body size, taller people generally have more elongated faces than shorter ones (Windhager et al. 2011) and heavier men have wider and squarer lower facial regions (Coetzee et al. 2010). Available evidence also indicates that people use the abovementioned or related facial cues to assess others’ body weight and height, and they are fairly accurate in their judgments (Re et al. 2013b). It was found that low brows, large chins, wide noses, and narrow mouths are morphological traits related to perceived dominance and strength in both natural and computer-generated faces (Toscano et al. 2014), and that physical strength is associated with rounder faces with wider eyebrows and more prominent jaws (Windhager et al. 2011). While these studies demonstrate that there are specific facial morphological features associated with formidability-related traits and that people pay attention to these traits, they do not demonstrate whether these particular features are indeed present in more formidable individuals. Using the geometric morphometric methods, Třebický et al. (2013) showed systematic differences in structural configurations of facial features, perceived aggressiveness, and actual fighting success in sample of professional fighters (although, the association between facial configuration and fighting success was restricted to heavyweight fighters). Shape regressions revealed that aggressive-looking faces are generally wider and have broader chins, more prominent eyebrows, and larger noses than less aggressive-looking faces.

Facial Width-to-Height Ratio (fWHR)

Currently, the most frequently investigated facial measure is the facial width-to-height ratio (fWHR or relative facial width) (Weston et al. 2007).

Previous studies found that fWHR is related to several behavioral and personality characteristics including aggressive behavior and perceived aggressiveness (Geniole and McCormick 2015; Haselhuhn et al. 2015), even in cross-cultural context (Short et al. 2012). Stirrat et al. (2012) found that narrow-faced men were more likely than wider-faced men to die by contact violence compared to other causes of death or homicide. In a sample of professional MMA fighters, the variation in fWHR is associated with actual fighting performance, perception of aggressiveness, fighting ability, body weight (but not height) (Třebický et al. 2015), and higher numbers and proportions of wins and longer fighting careers (Zilioli et al. 2014).

Future Directions

One, currently rather neglected aspect of formidability related research, is cohesiveness of coalitions that seems to influence the outcome of conflicts. Most of the studies conducted so far are aimed on only one specific scenario of physical confrontations, where only two opponents confront. Though, physical encounters among men are not limited solely to the two individual opponents and may frequently involve other, the allies. Of high adaptive importance would be the ability to assess the prowess of a potential opponent as that of a potential ally, in terms of deciding whether to enter the fight and pursue relevant joined activities. Assessments of formidability are therefore not relevant solely in the context of a potential opponent but also in the context of selection of allies. Some species, particularly social primates, assess alliances and cooperative value and show deference toward individuals with more allies or with the ability to deny benefits (Smuts et al. 1987). Men with higher fWHR also show some evidence of increased sensitivity to coalitional alliance (Stirrat and Perrett 2012).

Many factors were suggested to affect assessments of formidability; nevertheless, it is not yet fully understood how these assessments work in real-life situations. We propose a model of multi-

level assessments of formidability that tries to cover processes responsible for the fight-or-flight decision when faced with a potential antagonist. In terms of decision-making models, this would correspond to “The fast and frugal tree” model where an individual follows a decision-tree with an exit option after each attribute (Martignon et al. 2003). We suggest that assessment of potential opponents acts on multiple levels. Based on the knowledge of one’s own formidability, a resource holding power (Parker 1974) of each competitor is evaluated regarding the potential costs he can inflict and benefits he can gain from confrontation, so that the welfare trade-off ratios (Tooby et al. 2008) which help to recalibrate appropriate level of anger of rivals could be calculated (Sell 2011). In general, judgments of fighting ability seem to focus on overall probability of winning a fight. The first step, in such a multilevel fight-or-flight decision-making process, might depend predominantly on the overall size of the opponent, as suggested by the ratings of fighting ability in our previous study (Třebický et al. 2015). If one of the competitors is substantially larger (e.g., taller, more muscular, or bulkier), the smaller one surrenders and withdraws from the conflict. When the rivals have roughly equal sizes, a further level of assessment takes place – which might be related to the perception of bargaining potential such as the assessment of aggressiveness from facial features (Třebický et al. 2013). If both competitors feel equally formidable, the confrontation may get escalated.

Conclusion

Antagonistic conflicts with conspecifics are a fundamental factor influencing fitness in many social species, including humans. Fighting ability had profound implications in our evolutionary past and, in some communities, continues to have significant implications in contemporary societies. Evolution of adaptations that facilitate decision-making in potentially agonistic interactions is therefore expected, as the individual must determine whether it is best to fight, flee, or appease the prospective foe. According to the

recalibration theory of anger (Sell 2011), benefits of minimizing the costs of engaging in violent conflict are thought to have shaped adaptations for the assessment of others' capacity to cause physical harm.

The main aim of this chapter was to review evidence whether morphological features served as reliable cues to the actual formidability and whether our visual perception is sensitive towards such cues. Current body of evidence support this notion and show that morphological features predicts which of two opponents are likely to withdraw from an aggressive encounter and based upon converging results of current studies investigating competition in men, we can conclude that our morphological features are valid predictive cues of actual performance in physical fights and that raters are sensitive toward these cues. These studies demonstrate that there are specific morphological features associated with formidability-related traits and that people pay attention to these traits. Raters are able to distinguish the winner of consequent fights with accuracy higher than chance (Little et al. 2015); the winners are rated as better fighters, as stronger, more dominant and attractive, compared to losers (Little et al. 2015). Holistic facial shape analyses and simple facial features ratios showed systematic differences in structural configurations of facial morphology in successful competitors, compared to unsuccessful ones and between individuals perceived as more aggressive compared to less-aggressive ones (Třebický et al. 2013, 2015).

At first glance, it seems obvious that winning and losing in a physical fight is determined by physical strength and body size. Height and bulk are two physical characteristics that are easily observable traits that can be used to provide a relatively crude, albeit somewhat accurate, appraisal of fighting ability among adolescent males (Beaver et al. 2015). Although assortment of other factors like health, skill, hand–eye coordination, proper technique, and armaments may come at play.

Currently, the research mainly focused on thin slices of information provided by a single cue rated on a single behavioral/personality characteristic. However, our perception is not limited to gathering information through just one

perceptual modality, e.g., just with our sight and we do ascribe many characteristics based on a single slice of information. Utilizing multiple cues assessment and/or multiple characteristics rating, testing the agreement between modalities and scales, and their subsequent interplay remains a challenge for future studies.

We propose that the assessment of potential opponents acts on multiple levels, then simply based on first impressions. In this multilevel “fight or flight” decision-making model, individuals assess their potential competitors following a decision-tree with an exit option after each attribute. At the first level, the decision-making process might depend predominantly on the overall size comparisons.

Although, competition in humans becomes widely investigated area in behavioral sciences, we are still at realms of rather skin-deep understanding to how the assessments of potential opponents take place. Abovementioned evidence is an important contribution to emerging body of research concerning evolution of neurocognitive and behavioral processes fine-tuned toward perception and adequate behavioral responses toward potential opponents.

Definition

Filial infanticide is the deliberate killing of one's own child, usually during the first year of its life

Introduction

Filial infanticide is the practice by which a parent terminates its own offspring. According to the US Department of Justice, homicides of children under the age of 5 are most often perpetrated by a parent (Fig. 1). Though there are a variety of motives leading parents to commit filicide, the practice has been prevalent in both humans and animals throughout history and has held steady in the United States in recent decades, despite a precipitous drop in all other forms of homicide during that same period (Cooper and Smith 2011). At first glance, the killing of one's own child seems tremendously paradoxical, in terms of achieving reproductive success, due to the immediate reduction of fitness following the loss of offspring. Conversely, there may be an underlying evolutionary drive toward filicide in certain instances through the advancement of inclusive fitness. Certain filicide cases may actually facilitate a net gain of reproductive success despite the initial fitness loss resulting from the killing. As such, filial infanticide may act as a form of natural

Homicides of children under age 5, by relationship with the offender, 1980–2008

selection, advancing the success of the perpetrator through inclusive fitness.

Inclusive Fitness

The theory of inclusive fitness was first developed by W. D Hamilton, one of the leading evolutionary theorists of the twentieth century. He defined inclusive fitness as the support of successful offspring, and possibly grand-offspring, thus maximizing the success of favorable genes those offspring inherit (Hamilton 1964a). Personal fitness, or direct fitness, is a subset of inclusive fitness and is defined by the number of successful offspring that one produces. Inclusive fitness begins with personal fitness but extends to other strategies for long-term reproductive success. Inclusive fitness is also comprised of indirect fitness, measured by reproduction of an individual's relatives (Hamilton 1964b). Organisms may engage in kin selection, which helps to explain altruistic behaviors that further the reproductive success of close relatives despite personal cost, and still acquire fitness gains for the shared genes (Smith 1964). Interestingly, considering fitness at a level larger than the individual lends direct support to the gene-centric, rather than the individual-centric view of evolution (Dawkins 1976; Burt and Trivers 2006). The gene-centric view of evolution is currently the unifying theory of sociobiology. Recognizing the comprehensive nature of inclusive fitness is crucial to understanding the motivating forces of complex social behaviors.

In order to analyze the proximate motives of filicide, the nature of the relationship between parent and child must be explored. Of course, parents are motivated to care for their young in order to maximize overall survival rates and achieve reproductive success. Due to the inclusive fitness benefits gained by investing in successful offspring, parents provide care for their offspring with little to no reciprocity. However, parental care is a finite resource, and friction arises when offspring require a greater degree of care than a parent is prepared to offer. This results in a phenomenon called parent-offspring conflict by Robert Trivers, one of the founding theorists of sociobiology (Trivers 1974). Within this conflict, offspring must vie for parental investment against other competing factors,

including and especially their siblings. If an infant were to display early signs of deficiency, thereby requiring a higher degree of parental investment, a parent may choose to neglect the weakling in order to further invest in healthy individuals with a greater chance at ultimate survival. Therefore, evolutionary conflict leads to unequal allocation of parental investment favoring stronger offspring over vulnerable ones.

Filial Infanticide

In 1979, Sarah Blaffer Hrdy first classified potential motives of infanticide. Most were described as providing evolutionary benefit to the perpetrator. The first category is the exploitation of the infant as a resource, often through cannibalistic practices. Second is the elimination of resource competition. When the death of an infant will increase resource availability for the rest of the population, the perpetrators are almost never parents of the victim, who have little incentive to divert resources from their own inclusive fitness to that of others. Non-parents, however, may experience fitness gains by killing another's offspring in order to divert limited resources toward their own offspring. The third potential motive is sexual selection, wherein a male perpetrator terminates offspring that are not his own in order to reduce reproductive success of competitors and potentially gain access to fertile females. This form of infanticide serves to assert dominance in a group, maintain control over sexual partners, and increase reproductive success. These first three categories rarely apply to infanticide perpetrated by parents (Hrdy 1979).

Hrdy outlines the fourth potential motive for infanticide as parental manipulation: the elimination of an ill-timed, handicapped, or unhealthy infant in order to spare resources for offspring more likely to achieve success. This form of infanticide is always perpetrated by the parent of the infant and may even be driven by empathy, as discussed below. Rather than invest in an offspring that has little chance at ultimate survival, it may be favorable to end the infant's suffering early, for both the benefit of the child enduring the

pain and the parent investing resources attending to an infant that is unlikely to be reproductively successful. Parental manipulation appears to be the most common motive for filial infanticide because of its focus on maintaining reproductive fitness and terminating weak offspring in order to invest in healthy ones (Hrdy 1979). Filial infanticide may act as a potential solution, ensuring net reproductive success via direct and indirect fitness gains.

Inopportune Birth of Offspring

Lack of Childcare/Presence of Other Offspring

One instance in which infanticide leads to a potential advancement of inclusive fitness is through the termination of a mistimed infant. The moustached tamarin (*Saguinus mystax*) is a species of New World monkey in which the common social structure is that of very small groups with multiple adult males and communal alloparenting. A recent case study of these tamarins details how the lack of childcare and presence of other offspring at the time of birth may lead to infanticide (Culot et al. 2011). In this study, researchers observed a wild female tamarin kill her own infant when another female was pregnant and there were only 2–3 male helpers in the group. The perpetrator had given birth to numerous successful offspring in the past, when there had been 4–5 capable helpers present. Researchers suggested that this infant may have been terminated due to the low availability of male helpers at the time of birth. According to these researchers, “the possible maternal infanticide reported fits the parental manipulation hypothesis and can occur in a group with a poor capacity to raise offspring with multiple breeding females, with birth intervals shorter than 3 months, combined with an estimated low infant survival probability.” Indeed, the number of helpers (and their ratio to the number of infants) in a group directly correlates with infant survival rates (Culot et al. 2011).

Humans face comparable challenges relating to the lack of childcare and presence of other offspring, acting as a contributing factor in cases of infanticide (Bourget et al. 2007; Daly and

Wilson 1988, p.51). The Ayoreo peoples are nomadic hunter-gatherers indigenous to the central plains of South America, some tribes of which remain uncontacted or minimally so. A striking degree of filial infanticide has been reported in this population and follows a consistent pattern. Bugos and McCarthy studied filicide within the Ayoreo Indian population and found that infants born to women with limited resources and male protection are commonly terminated immediately following birth. Survival of a healthy newborn in the Ayoreo community is highly dependent upon a mother’s physical and social support, or lack thereof, at the time of birth (Bugos and McCarthy 1984). In Canada, perpetrators of maternal infanticide tend to be younger and unwed, with single mothers committing over half of the maternal infanticide cases reported to police (Daly and Wilson 1987, 1988). Interestingly, a cross-cultural study showed a dramatic reduction of infanticide cases in societies in which social relief was offered to lighten maternal burden, supporting the view that infanticide is linked to ecological factors (Granzberg 1973).

An infant born at an inopportune time, when the parent faces economic stress with limited childcare options, carries a greater than normal burden to parents (Smithey 1997). This is especially true when prior offspring are still dependent on parental care, whose survival is placed at greater risk when subsequent children are born (Hrdy 1979). Therefore, inopportune birth timing may be a contributing motive for filial infanticide. Termination of the infant could result in an increase of inclusive fitness by allowing the perpetrator to distribute proper investment in other current or future offspring.

Economic/Resource Stress

Another potential factor in filicide is economic stress. In 2002, cases of maternal infanticide in the Federal Bureau of Investigation’s Supplemental Homicide Reports were cross-referenced with the US Census information to reveal those in which financial instability may have played a role. The combined data indeed exhibits a correlation between economic stress and infanticide (Gauthier et al. 2003). This corroborates an earlier

study in which researchers analyzed interviews of infanticide perpetrators in Texas and found that unstable economic conditions along with a lack of interpersonal support was a common theme specific to the filicide cases (Smithey 1997).

An ethnographic study of the Yānomamō tribal peoples also recorded circumstances of infanticide in which a newborn is at risk of termination if born in close proximity to an older sibling, causing resource competition between the two for milk (Chagnon 1968). Similarly, Ayoreo women are more likely to commit infanticide when a child is born too soon following the birth of a previous one (Bugos and McCarthy 1984). Resource scarcity lends itself to competition between siblings (Trivers 1974), potentially leading to parental intervention in the form of infanticide to ensure survival of older children, for whom more investment has already been expended.

These reports suggest that, both in humans and tamarins, if a mother suffers from economic/resource instability or a lack of childcare support, she is more susceptible to perpetrating infanticide (Gauthier et al. 2003; Smithey 1997). When resources become limited, siblings are placed in competition against one another (Trivers 1974). Therefore, the termination of an infant could advance inclusive fitness in certain instances if it allows the perpetrator to invest limited resources in other current and/or future offspring and increase their chance of survival.

Parental Perception of Fitness

In 1998, in a band of wild saddle-back tamarins (*Saguinus fuscicollis*), researchers watched as a newborn was killed and partially consumed by its mother after having fallen from its carrier numerous times (Herrera et al. 2000). The researchers inferred that the motive behind the filicide was parental manipulation, likely due to the perceived damage that the several falls had inflicted. Though the newborn had actually sustained minimal visible damage (Herrera et al. 2000), its mother may have chosen to remove investment in the child early on because she

perceived the falls themselves as an early sign of weakness.

Researchers concluded that the mother's motive behind the infanticide was most likely in line with Hrdy's parental manipulation hypothesis (Hrdy 1979). Meat exploitation was ruled out because only the head and brain of the infant were consumed, ignoring the rest of the body. Additionally, the tamarin's bite was inconsistent with its usual killing bite used with prey. The categories relating to sexual selection and resource competition were also ruled out, given that this was a case of filial infanticide in which the mother killed her own child (Herrera et al. 2000).

Similarly, in 1985, it was reported that Brazilian shantytown mothers tend to entirely remove parental investment when they perceive a child to have a physical or developmental disability, purposefully withholding care and food (Scheper-Hughes 1985). Early on, mothers tend to prefer babies with characteristics of a "fighter" and "survivor," and passive babies are deemed as "good for nothing" (Scheper-Hughes 1985). Though the infants are not typically terminated by direct infanticide, the removal of parental investment leads to the same fate (Daly and Wilson 1987). Similar attitudes toward weak or deficient infants have been recorded in history and pseudo-historical folklore. For example, the Spartans of Ancient Greece were said to have eliminated weak children from their population in order to perfect the army (Melillo 2017). More recently, Ayoreo Indian mothers have been reported to terminate newborns displaying signs of illness or deformity due to perceived weakness and limited survivability (Bugos and McCarthy 1984). Like behavior has also been found in the Aymara community in Andes of Bolivia, where biological defects were viewed as justification for infanticide (de Hilari et al. 2009). Indeed, a cross-cultural analysis by Martin Daly and Margo Wilson noted 21 societies in which the rejection of a newborn of poor health could be categorized as an adaptive parental response (Daly and Wilson 1984).

These studies unify Trivers' parental investment theory and Hrdy's parental manipulation hypothesis. Therefore, at least in extreme

conditions of limited resources or alloparental care, parental perception of offspring's health and vigor is vital to infant survival, given that a mother's investment is directly related to her perception of the child's fitness early on. In both humans and tamarins, the infanticide of offspring with a seemingly slim chance of ultimate survival may advance the parent's inclusive fitness.

Empathy and Altruism

Altruistically motivated homicide, known colloquially as euthanasia, may be the most common mode of filial infanticide (Resnick 1969). An altruistic act is one performed out of selfless concern for the well-being of another despite cost incurred, however small, to the actor. Perpetrators of altruistic filicide are thus driven to spare their child physical or mental suffering (Bourget et al. 2007; Friedman et al. 2005; Resnick 1969), and empathy is the proximate cause of the act. Of note, some cases of altruistic infanticide are based on a deluded belief of the child's suffering (Bourget et al. 2007; Friedman et al. 2005). Hrdy calls this "social pathology" (Hrdy 1979) because these acts are likely maladaptive. However, true altruistically motivated filicide, in which the suffering of the child is real, may indeed be regarded as adaptive through inclusive fitness gains in some cases.

In Australia, researchers found that altruism plays a primary role in the termination of infants by their mothers (Eriksson et al. 2016). In one instance, an infant was suffering from a chronic disability, and his mother sought an end to his struggles and pain. Another infant was terminated due to recent episodes leading to an unstable home environment and the mother's fear that the child would be irreversibly traumatized. In both cases, the homicides were driven by empathy with the aim of alleviating their child's suffering. Additional studies have documented altruistically motivated filicide as a worldwide phenomenon (Gowda et al. 2018; Razali et al. 2015). Though empathy may be the proximate drive of these filicides, gains in fitness may still underpin the ultimate mechanisms by allowing the parent to invest in future healthy offspring.

Discussion

When considering the evolutionary roots of behavior, it is necessary to differentiate between proximate cause and ultimate cause. According to Ernst Mayr, "proximate causes govern the responses of the individual (and his organs) to immediate factors of the environment whereas ultimate causes are responsible for the evolution of the particular DNA code of information with which every individual of every species is endowed" (Mayr 1961). A proximate cause is an immediate and mechanistic response driving an action. On the other hand, an ultimate cause serves as the greater evolutionary reason for the act to persist, focused on the natural selective forces at play and the resulting fitness gains of the act. Individuals may understand the proximate drive of their actions, but ultimate mechanisms are almost always hidden from their awareness.

Though filial infanticide may bring an immediate cost to the parent's fitness, given the resulting loss of offspring, the act may still advance overall inclusive fitness in the long run. Factors predicting such cases are inconvenient timing (with relation to finances, childcare options, and the presence of siblings), the presence of weakness and/or physical defects, and empathy for a suffering child. Because infanticide lessens economic burdens and removes stressors prohibiting the parent from caring for other offspring (whether they be future or current), a gain in inclusive fitness is possible. Infanticide of offspring perceived to be weak or deficient, whether the act is motivated by empathy or not, may also advance inclusive fitness for similar reasons. The foreseeable advancement of a parent's inclusive fitness may be the ultimate mechanism underpinning infanticide. In the case of altruistic filicide, in which the perpetrator is acting out of a selfless concern for its child, empathy may be of proximate cause, driving the act itself. However, inclusive fitness is still likely to be the ultimate cause. Altruistic filicide allows a parent to give rise to future healthy offspring with only minimal investment given to a weak one, while simultaneously alleviating the suffering of the infant in question.

Homicides of children under age 5, by age of victim, 1980–2008

Filial Infanticide in Humans and Other Primates, Fig. 2 Infanticide risk increases with age, with the highest number of victims aged less than 1 year. (Retrieved from: Cooper and Smith 2011)

The demographic data on filial infanticide in humans support this theory. The overwhelming majority of infanticide victims are less than 1 year of age upon termination and the risk of infanticide decreases with age (Fig. 2; Cooper and Smith 2011; Fox and Zawitz 1999). This can be interpreted through the lens of Trivers' parental investment theory: the earlier the termination occurs, the more resources are preserved. It is also relevant to note here that parental cost is heavily front-loaded in mammals and steadily declines with the age and developmental independence of the offspring.

In most cases, the fitness of current and/or future siblings is favorably impacted by infanticide through the resulting boost in parental investment. The elimination of a competitor, their sibling, ultimately furthers their likelihood of survival (Trivers 1974). According to Hrdy and Hausfater, "The death of an infant and termination of parental investment will sometimes improve the chances for survival of either the mother or her older offspring [possibly both] or will otherwise lead to the greater net reproductive fitness for the mother of the infant, the father, or both" (Hausfater and Hrdy 1984). The filicide of an infant instantly lowers the number of offspring vying for care, increasing the amount of parental

investment and resources available to the remaining siblings.

Conclusion

Further research into the behavioral ecology of filicide is needed. There is a dearth of recent empirical studies documenting the impact that infanticide has on current siblings. Such studies would provide powerful evidence in support or refutation of the parental investment-based theories of filial infanticide. Further, with greater confidence in the ultimate mechanism of filial infanticide, we can bolster support for policies that reduce its prevalence in humans. For example, guaranteed socialized support for the childcare, healthcare, and education of children, especially infants, may reduce the degree of perceived parental investment necessary for the thriving of a newborn, especially those with special needs. This, in turn, could reduce the perception that children compete with each other for limited time, attention, and resources from parents. The reduced perception of competition could undercut the evolutionary psychological triggers that drive filial infanticide and, potentially, save lives.

Filicide

Vibeke Ottesen

Department of Bioscience, Centre for Ecological and Evolutionary Synthesis (CEES), University of Oslo, Oslo, Norway

Synonyms

Child homicide; Familicide; Infanticide; Neonaticide

Definition

Filicide is the killing of an underage victim by a caretaker (i.e., genetic parent or stepparent). Filicides are conventionally categorized as infanticide if the victim is <1 year of age and neonaticide when the victim is killed <24 h after being born.

Introduction

Evolutionary psychologists Martin Daly and Margo Wilson (1988) proposed the hypothesis that homicides, including filicide, occur in the context of reproductive conflicts. A reproductive conflict occurs when the fitness interests (i.e., interests pertaining to the potential number of offspring sired) one individual has come at a cost to the fitness interests of another individual. It may at first seem contradictory that there could occur reproductive conflicts between offspring and their caretakers, as they share the evolutionary significant interest in the offspring's eventual reproduction. However, as the scholarly works of evolutionary theorists such as Richard Alexander (1979), William D. Hamilton (1964), and Robert Trivers (1972, 1974) collectively inform on, there are circumstances in which a caretaker's investment of resources in a given offspring may not necessarily reward the caretaker with an equivalence of fitness return. In such circumstances there arises a reproductive conflict with regard to the level of investment the caretaker makes in the offspring. The works of these evolutionary theorists further inform on the fact that caretakers who identify circumstances in which the potential fitness returns of their investment may not be rewarding, and adjust their level of investment accordingly, may ultimately leave more offspring than those caretakers who lavishly invest in all offspring in their care regardless of the potential fitness return. This will, in turn, inevitably lead to the evolution of the ability to perform discriminant parental investment in the species in question.

Daly and Wilson (1988) noted that there is no theoretically sound reason to expect that humans

have been immune to the selection processes favoring individuals with the ability to perform discriminant parental investment. Fostering children to reproductive maturity in our species is dependent on relatively high levels of investment over a prolonged period of time. And in our ancestral past, these resources would be limited and finite for each individual caretaker. In conditions where the caretaker's investment would not guarantee a fitness return (e.g., the survival of offspring to reproductive maturity), investing these resources indiscriminately would, in evolutionary terms, be an irrevocable waste. Drawing on this knowledge, Daly and Wilson proposed that filicide may occur as a rare and extreme result of discriminant parental investment, where the parent's solicitude towards the child is accidentally lowered to lethal levels.

Although homicide is a behavioral action, Daly and Wilson (1988) argued that adaptation must be sought at a psychological rather than behavioral level when studying its perpetration. They proposed that there are psychological mechanisms that are triggered when individual caretakers assess whether and how much to invest in a given child in their care. These mechanisms may elicit a range of behavioral responses, including violence and neglect at both lethal and nonlethal levels. According to Daly and Wilson, it is these psychological mechanisms that are the products of evolutionary selection forces and not the range of behavioral responses that may be performed. Thus they proposed that filicide is an epiphenomenon, a by-product of evolved psychological mechanisms that have the adaptive function of enabling the individual to perform discriminant parental investment.

Later, evolutionary psychologists Joshua Duntley and David Buss (2008, 2011) proposed that there are psychological mechanisms which have been selected for the specific function of eliciting homicide perpetration – including filicide. They argued that psychological mechanisms that specifically elicit filicide perpetration would be favored by evolutionary selection processes because killing a child would ensure a more abrupt and lasting prevention of any potential

waste of finite resources than a mere nonlethal reduction in parental investment would.

Disaggregating Filicide to Identify Patterns in Characteristic Traits

Considering under what circumstances a conflict over parental investment might arise in our species' ancestral past, Daly and Wilson (1988) disaggregated filicide into subcategories depending on the perpetrators sex, genetic relationship to the victim, and psychopathology. In doing so, they uncovered a unique pattern of characteristic traits for each subcategory.

Disaggregating Genetic Parents and Stepparents as Perpetrators

As genes are the unit for evolutionary selection, the reproductive value of an offspring to a caretaker is, at least in part, conditional on their genetic relatedness. The greatest potential for a reproductive conflict may therefore be in the absence of relatedness (Alexander 1979; Hamilton 1964). It is therefore expected that caretakers will experience a greater reluctance towards investing in stepchildren than in their genetically related children (Daly and Wilson 1988, 1994, 2001; Duntley and Buss 2008, 2011). And it is therefore expected that filicides perpetrated by genetic parents and stepparents will differ in their characteristic trait. Firstly, it is predicted children living in stepparental households will be at an increased risk for victimization compared with households with two genetic parents. Secondly, it is predicted that stepparental perpetrated filicides will be characterized by the caretaker's hostility towards the victim and lapses in parental solicitude. Specifically, it is predicted that stepparents will typically perpetrate fatal abuse. In contrast, genetic parents are predicted to more often have altruistic motives for their filicides and thus be more likely to perpetrate their homicides by methods that limit their victims' suffering.

Studies that disaggregate filicides perpetrated by stepparents and genetic parents lend

empirically support the above predictions. For instance, Daly and Wilson (1994) found in a Canadian national sample, 1974–1990, that victims were 60 times more likely to be killed by a stepparent than a genetic parent and further that stepparental perpetrators were 120 times more likely to beat their victims to death than genetic parents were. In contrast, genetic parents were more likely to shoot or asphyxiate their victims. Similar findings are confirmed in other samples from Canada (Daly and Wilson 1988; Harris et al. 2007; Wilson et al. 1995), the USA (Daly and Wilson 1988; Weekes-Shackelford and Shackelford 2004), Australia (Alder and Polk 2001), the UK (Flynn et al. 2013; Daly and Wilson 1994; Wilson et al. 1995), the Netherlands (Liem and Koenraadt 2008a), Finland (Vanamo et al. 2001), and Sweden (Daly and Wilson 2001; Nordlund and Temrin 2007; Somander and Rammer 1991; Temrin et al. 2004, 2011).

The listed studies have explored the characteristics of filicides perpetrated by stepfathers. One may however expect that living with a stepmother may pose an equal, if not greater, risk for filicide (Harris et al. 2007). As mothers make greater parental investment in children than fathers, in terms of direct physical resources and therefore also time, the reproductive cost of investing in a genetically unrelated child may be greater for women than for men. The potential for reproductive conflict over parental investment may thus be greater when the caretaker is a stepmother than a stepfather.

Two studies on filicide that included stepmaternal perpetrators have been performed on a Canadian national sample, 1997–2003 (Harris et al. 2007), and a US national sample, 1976–1994 (Weekes-Shackelford and Shackelford 2004). Both studies found an overrepresentation of both stepmaternal and steppaternal perpetrators compared to genetic parents. Further, in the Canadian study, Harris et al. (2007) had access to data that revealed that children victimized by their stepmothers had experienced harsher treatment leading up to the homicide compared to children victimized by stepfathers or genetic parents of either sex.

Disaggregating Maternal and Paternal Perpetrators

When a species has two sexes that contribute different levels of parental investment and face different challenges in securing reproductive success, heritable sex-differentiated traits may evolve (Trivers 1972). Taking into account the unique challenges that faced ancestral women and men, respectively, Daly and Wilson (1988) proposed sex-differentiated psychological mechanism underpinning filicide perpetration and predicted that the characteristics of such homicides would differ with maternal and paternal perpetrators, respectively.

To secure the highest potential reproductive success across a life span, individuals calculate how much parental investment to allocate in present versus future offspring. Such calculations may be conscious, but they may also be performed on a level the individual is not conscious of and influenced by processes the individual is not aware. Daly and Wilson (1988) noted that as the individual's residual reproductive potential (fecundity) decreases with age, the potential for having or replacing an offspring also decreases. From this biological fact, they proposed that genetic parents would be less discriminant in their investment in children with age. Specifically, they predicted that a caretaker's young age would be associated with an increase in the risk for filicide. Because reproductive fecundity declines at an earlier age for women than for men, they further predicted that maternal perpetrators would be younger than paternal perpetrators.

There is empirical support for their predictions cross-culturally. For instance, in a Fijian national sample, 1993–1996, the mean age of maternal filicide perpetrators was 25 years, whereas the mean age of paternal perpetrators was 30.3 years (Adinkrah 2000, 2001, 2003). Similar findings have been confirmed in samples from the USA (Friedman et al. 2005), the Netherlands (Liem and Koenraadt 2008a), and Finland (Kauppi et al. 2010; Vanamo et al. 2001).

As women gestate and nurse, they make more direct and heavy investments in the youngest children. It is therefore predicted from EP perspectives that the youngest children would be at an

increased risk of victimization by their mothers (Daly and Wilson 1988; Duntley and Buss 2011). There is empirical support for this prediction cross-culturally. For instance, in a Finnish national sample, 1970–1994, mothers perpetrated 90% of the filicides where the victim was killed during their first year of life (Kauppi et al. 2010). Similar findings have been confirmed in another Finnish samples (Vanamo et al. 2001), and in samples from the USA (Overpeck et al. 1998), Canada (Harris et al. 2007), the UK (Flynn et al. 2007, 2013), Fiji, (Adinkrah 2000, 2001, 2003), the Netherlands (Liem and Koenraadt 2008a), Denmark (Laurssen et al. 2011), and Sweden (Nordlund and Temrin 2007; Somander and Rammer 1991).

Considering the amount of resources required to foster a child to reproductive maturity, one may expect that it would have more often than not required two parents in our ancestral past. Further, having a child from a previous union may have been an impediment for future relationships, as potential new partners could perceive a stepchild as a reproductive burden. It has therefore been proposed that single parenthood may increase the risk for a reproductive conflict between a caretaker and child (Daly and Wilson 1988; Duntley and Buss 2011) and further predicted that children will be at an increased risk for victimization in households with a single caretaker compared to households with two genetic parents. Theoretically, single parenthood may be an important cue for discriminative parental investment for women and men equally. And in a Swedish national sample, 1965–1999, where maternal and paternal perpetrators were not disaggregated, 32.2% of the victims lived with a single parent, yet only 12.6% of the children in the general population lived with a single parent (Temrin et al. 2004). However, the rates of single mothers in the general population are greater than the rates of single fathers. And there is cross-cultural empirical support for that single parenthood is characteristic of maternal perpetrators. For instance, in a British national sample of infanticides, 1996–2001, less than half the mothers were either married or cohabiting with a partner at the time of perpetration (Flynn et al.

2007). Similar findings have been confirmed in the USA (Friedman et al. 2005; Overpeck et al. 1998; Stone et al. 2005), Canada (Daly and Wilson 1988; Harris et al. 2007), Australia (Alder and Polk 2001), Fiji (Adinkrah 2000, 2001), and Italy (Camperio Ciani and Fontanesi 2012).

A reproductive challenge that has been singular to ancestral men is the potential uncertainty as to whether or not a child in their care is their genetic offspring. It has therefore been argued that evolutionary selection would favor psychological mechanisms among men that would protect against being cuckolded. Such mechanisms may include a heightened sensitivity to cues of and concern with a partner's sexual infidelity and proprietary feelings towards their partner. It has further been proposed that there will be sex-differentiated motives for partner homicide. Specifically, it has been predicted that there will be an increased risk for male-perpetrated partner homicide when the woman has left or intends to leave the relationship (Daly and Wilson 1988; Duntley and Buss 2008; 2011).

There is empirical support for this prediction, as sexual jealousy and female-initiated relationship dissolution are the context in which intimate partner homicides most frequently occur (e.g., Daly and Wilson 1988; Shackelford et al. 2003).

From the same reasoning, it has further been predicted that familicide (i.e., homicides where a current or former intimate partner and one or more children are killed) will predominantly be perpetrated by men and occur in the context of the woman actually or potentially leaving the relationship (Harris et al. 2007; Wilson et al. 1995). There is empirical support for these predictions cross-culturally. For instance, 93% of familicides in Canada, 1974–1990, and 96% of familicides in the UK, 1977–1990, had male perpetrators (Wilson et al. 1995). Further, the children were rarely the objects of conflict that elicited the familicide. Rather, the familicide was elicited by a relationship dissolution initiated by the woman. Similar findings have been confirmed in other Canadian and UK samples (Daly and Wilson 1988, 1994; Harris et al. 2007) and in samples from the USA (Friedman et al. 2005), Australia (Alder and Polk 2001), Fiji (Adinkrah 2001,

2003), the Netherlands (Liem and Koenraadt 2008b), Finland (Kauppi et al. 2010;), and Sweden.

It has further been predicted that men may perpetrate filicide as part of their attempt to control and punish their current or former partner at a higher rate than women (Harris et al. 2007; Wilson et al. 1995). There is empirical support for this prediction cross-culturally. For instance, in a Swedish national sample, 1965–1999, 72% of the cases that occurred during interpersonal conflict where the motives appeared to be jealousy or revenge on a current or former partner had a male perpetrator (Nordlund and Temrin 2007). Similar findings have been confirmed in other Swedish samples (Somander and Rammer 1991; Temrin et al. 2000) and in samples from Canada (Harris et al. 2007), Australia (Alder and Polk 2001), the Netherlands (Liem and Koenraadt 2008b), and Finland (Kauppi et al. 2010).

From an EP perspective, it has further been proposed that the proprietary feelings men may have towards their partners and children could be associated with their ancestral role as the main providers for the family (Harris et al. 2007; Wilson et al. 1995). It has therefore been predicted that men will be more likely than women to perpetrate filicide and familicide in association with a threat to their role as a provider. There is cross-cultural empirical support for this prediction. In the abovementioned Swedish study, all but one of the filicides that appeared to be motivated economic hardship had a male perpetrator (Nordlund and Temrin 2007). In four of the seven incidents, the male perpetrator killed the whole family. Similar findings have been confirmed in other Swedish samples (Somander and Rammer 1991) and samples from Canada (Daly and Wilson 1988), the USA (Friedman et al. 2005), and Fiji (Adinkrah 2001, 2003).

Disaggregating Perpetrators with Psychopathology

From an EP perspective, psychopathology may be understood as mental states in which the individual no longer perceives or acts in accordance with his or her reproductive interest (Daly and Wilson 1988; Wilson et al. 1995). From this perspective

one may infer the hypothesis that filicides that contradict adaptive logic will be associated with perpetrator psychopathology (e.g., psychosis or suicidal ideation) at a higher rate than those filicides that do not contradict this form for logic (Daly and Wilson 1988; Duntley and Buss 2008; Stone et al. 2005). A series of predictions concerning the characteristics of filicides associated with perpetrator psychopathology follow from this hypothesis.

As the potential reproductive value of a child partly depends on the genetic relationship to the caretaker, one may predict that there will be a higher rate of psychopathology among genetic parents than among stepparents who perpetrate filicide. There is empirical support for this prediction cross-culturally. For instance, in a Swedish national sample, 1971–1980, half of the genetic parents committed suicide in conjunction with the homicide (29 of 58), whereas only a quarter of stepparents did so (one of four) (Somander and Rammer 1991). Similar findings have been confirmed in other Swedish samples (Nordlund and Temrin 2007) and in samples from the USA (Shackelford et al. 2008), Canada (Daly and Wilson 1988, 1994; Harris et al. 2007; Wilson et al. 1995), the UK (Daly and Wilson 1994; Flynn et al. 2013; Wilson et al. 1995), and Finland (Kauppi et al. 2010). However, in a study of filicides in Chicago, 1965–1994, there was no significant difference between stepparents and genetic parents in their suicide rates (Shackelford et al. 2005). According to Shackelford and colleagues, this is the only known study where there is no significant difference between the suicide rates of the two perpetrator categories. Shackelford and colleagues attributed their finding to the small percentage of genetic parents that commit suicide in their sample.

Because the potential reproductive value of an offspring to its caretaker increases as it reaches reproductive maturity, killing an older child is potentially a greater compromise to a caretaker's reproductive success than killing a younger child. It is therefore predicted that there will be a higher rate of psychopathology among perpetrators with older victims than younger victims (Stone et al.

2005). There is empirical support for this prediction cross-culturally. For instance, whereas the rate of lifetime history of mental disorder found among perpetrators of infanticide in England and Wales, 1996–2001, was similar to that of the general population, there was a correlation between an increased risk for suicide and an increase in the victims' age (Flynn et al. 2007, 2013). Similar associations between perpetrators' psychopathology and victims' age are confirmed in other samples from the UK (d'Orban 1979) and from the USA (Friedman et al. 2005; Shackelford et al. 2005, 2008; Stone et al. 2005), Canada (Daly and Wilson 1988b; Harris et al. 2007), Australia (Alder and Polk 2001), Fiji (Adinkrah 2000, 2001, 2003), Italy (Camperio Ciani and Fontanesi 2012), and Finland (Haapasalo and Petäjä 1999; Kauppi et al. 2010).

As an individual's residual reproductive potential is reduced with age, it is predicted that an increase in the perpetrators' age will be associated with an increased probability for perpetrator psychopathology (Stone et al. 2005). There is empirical support for this prediction cross-culturally. For instance, in a Chicago sample, 1965–1994, Shackelford et al. (2005) found that, among genetic parents, there was a greater percentage of perpetrators who were 26 years or older who commit suicide in conjunction with the filicide than perpetrators who were younger (10.8% and 1.5% of the two age groups, respectively). Similar findings have been confirmed in other US samples (Friedman et al. 2005; Shackelford et al. 2008; Stone et al. 2005) and in samples from Canada (Daly and Wilson 1988; Harris et al. 2007), Australia (Alder and Polk 2001), the UK (d'Orban 1979; Flynn et al. 2007, 2013), Italy (Camperio Ciani and Fontanesi 2012), and Finland (Kauppi et al. 2010).

A final prediction concerning filicides associated with psychopathology is that they are more likely to have multiple victims than filicides without such an association. There is empirical support also for this prediction cross-culturally. For instance, in Canadian national sample, 1974–1990, Wilson et al. (1995) found that familicidal perpetrators commit suicide more often than single-victim perpetrators (50.9% and

25.3%, respectively). Similar findings have been confirmed in other Canadian samples (Daly and Wilson 1988) and in samples from the USA (Freidman et al. 2005; Shackelford et al. 2005, 2008; Stone et al. 2005), Australia (Alder and Polk 2001), the UK (d'Orban 1979; Flynn et al. 2013; Wilson et al. 1995), Finland (Kauppi et al. 2010), Denmark (Laursen et al. 2010), and Sweden (Nordlund and Temrin 2007; Somander and Rammer 1991).

Criticism against Evolutionary Psychological Perspectives on Filicide

Criticism against evolutionary psychological perspectives on filicide has mostly focused on whether the cross-culturally confirmed overrepresentation of stepparental perpetrators reflects objective realities or, if so, what alternative explanations than current evolutionary psychological perspectives might there be for this overrepresentation. One of the more prominent critics of evolutionary psychology, the philosopher David Buller (2005), has argued that the overrepresentation may be due to a systematic bias, whereby stepfathers are more likely to be detected and reported than genetic fathers. However, as noted, Buller's conclusion is highly unrealistic considering the number of undetected filicides it implies. With "estimated rates of fatal batterings of Canadian children under 5 years of age in 1974–1990 at 2.6 deaths per million child-years at risk for those residing with and killed by their (presumed) genetic fathers (based on 74 deaths in 28.3 million child-years at risk) versus 321.6 per million child-years at risk for those residing with and killed by stepfathers (55 in 0.17 million child-years at risk). The latter rate is more than 120 times higher than the former. To give Buller's argument its best chance, suppose for the moment that stepfathers were always caught whereas genetic fathers often got away with murder; even so, for the "true" rate of fatal batterings by genetic fathers to equal that for stepfathers, there would have to have been more than 500 undiscovered paternal murders each year in addition to the annual average of 4 that were detected."

Buller's unlikely conclusion might have been due to a lack of calculation of the extent the potential detection bias against stepparent would have to be to annul their overrepresentation in official records. Other critics have based their conclusion of a lack of overrepresentation of stepparental perpetrators on calculation errors. This was the case for Temrin et al. (2000) who concluded that stepparents were not overrepresented as perpetrators in Sweden, 1975–1995. Daly and Wilson (2001) corrected this error and found that stepparents were in fact overrepresented, albeit to a lesser extent than that found in previous studies in other types of societies. Daly and Wilson (2001) further criticized Temrin and colleagues for not presenting their finding, assuming it had been correct, as a local exemption, but rather as disproving the hypothesis of discriminant parental investment depending on genetic relatedness and thus ignoring the overwhelming support the hypothesis has received cross-culturally (see also Temrin et al. 2011 for similar conclusion). A local exemption for the level of risk for stepparental perpetrated filicide in a modern welfare society, such as Sweden, would be more theoretically sound than that an evolved human parental psychology would not be discriminant depending on genetic relationship.

Conclusion concerning a lack of significance of genetic relationship for parental investment may have been due to a theoretical misconception of evolutionary psychology as advocating determinism. It is crucial to note that the proposal of evolved psychological mechanisms is not a proposal of determinism. With its theoretical foundation firmly placed in modern evolutionary biology, evolutionary psychology stresses the importance of the individual's environment for eliciting a manifestation of evolved psychological mechanisms. In other words, the expression of evolved psychological mechanisms is context specific – triggered and manifested only under evolutionary salient cues in the environment. From an evolutionary psychological perspective, filicide rates are not expected to be invariant between societies, nor are the rates of different perpetrator categories expected to be invariant between societies. Rather, cross-national

variations in the magnitude of risk are expected, as the psychological mechanisms that may lead to filicide are activated by circumstances that are salient cues to reproductive conflicts. For instance, it is expected that the risk stepparents will pose for filicide in a given society will be closely associated with cues for extreme discriminative parental investment (e.g., if it is a social or economic burden caring for stepchildren) (Daly and Wilson 2001). It is therefore not a threat to the validity of the evolutionary psychological perspectives that different societies do show different rates for the risk for filicide in general or for different perpetrator categories. It is actually to be expected that, for example, whereas the risk for victimization by a stepfather was 100 times higher than the risk for victimization by a genetic father in the USA in 1972 and 70 times higher in Canada, 1974–1983 (Daly and Wilson 1988), the risk was reduced in Sweden, 1965–2009, to a rate where perpetrators per million parents per year was 1.9 for genetic parents and 3.2 for stepparents ($p = 0.008$) (Temrin et al. 2011).

Daly and Wilson (2001) argued that a possible explanation for why stepparents were not over-represented as filicide perpetrators to the same extent in current day Sweden as in other types of societies is the alleviation of pseudoparental obligation of stepparents in modern, well-developed welfare societies. As parental investment required from stepparents is reduced in such societies, this will in turn alleviate potential reproductive conflicts in step-relationships, thus decreasing the risk for filicide. Daly and Wilson (2001) further argued that as fatal abuse is less likely to occur in societies where corporal punishment of children is illegal, such as in current-day Sweden, filicide perpetration by fatal abuse might be an inappropriate assay for measuring discriminant parental investment in such societies.

A second example of a possible theoretical misunderstanding concerning determinism by critics of evolutionary psychology is seen in homicide researchers Alder and Polk's (2001) suggestion that the fact that not all stepparents perpetrate filicide somehow undermines EP perspectives on stepparental perpetrators. However, as in most psychological research and research on

the patterns in characteristic traits of homicide, evolutionary psychological perspectives search for tendencies on group levels. The proposed predictions concerning the patterns in characteristic traits for filicide are therefore not expected to be absolute – one does not expect every single family who shares the listed characteristic traits to be associated with an increased risk for filicide to be determined for filicide. Just as explanations at a proximate level of analysis for the overrepresentation of stepparental perpetrators, such as jealousy or lack of attachment to a stepchild, do not imply that filicide is determined to occur at the hands of stepparents or in the context of such emotions, merely statements of what contexts might increase the risk for filicide perpetration.

However, a truly comprehensive theory for understanding filicide should however account for the apparent individual differences caretakers have in their risk for perpetration. Only a small fraction of caretakers who find themselves in circumstances associated with an increased risk actually perpetrate filicide, and current evolutionary psychological perspectives lack an explicit account of why individuals would differ in this way in similar circumstances.

Conclusion

Drawing on theoretical and empirical knowledge from the fields of evolutionary theory and biology of how discriminant parental behavior inevitably evolves, evolutionary psychologists have derived the hypothesis that filicide occurs in the context of reproductive conflicts and as an extreme outcome of discriminative parental investment. This hypothesis has in turn catered a comprehensive theoretical foundation for disaggregating filicide into meaningful subcategories, depending on the perpetrators' sex, genetic relationship to the victim, and psychopathology. The hypothesis has further enabled the successful prediction of the characteristic traits of the respective subcategories. As the predictions derived from the hypothesis have gained cross-cultural, empirical support, the validity of the hypothesis has become strengthened.

Financial and Hierarchy Maintenance

Jessica D. Fields
University of Missouri, Columbia, MO, USA

Definition

The need to maintain social hierarchy social status will lead individuals to make matrimonial decisions based on social connections and financial status. As such, individuals may restrict potential marriage partners through set marriage patterns

such as endogamous marriage, marrying within a specific group, or isogamous marriage, marrying someone of equal status. In rare cases, hypergynous marriages may also occur where an individual will marry into a higher social class or social status. This need to preserve social rank and financial status will also extend into inheritance patterns with specific offspring being selected as the preferred heir. Historically this most often took the form of primogeniture with the eldest son being the preferred inheritor (Hrdy 1992, 1993).

Introduction

Among societies with heritable wealth, a scarce resource, specific inheritance patterns will develop which are designed to guarantee the financial and hierarchical status within families and/or social classes. This pattern can be seen clearly in historic aristocratic families who arranged and secured marriages and alliances, which were designed to best preserve the social status and wealth of ruling families.

Heritable Wealth

Heritable wealth can take multiple forms: land, livestock, money, titles, or other forms of wealth. Social status can also be part of the transmission of wealth from one generation to the next. The transmission of wealth can take several forms including primogeniture (eldest child, often the eldest son), ultimogeniture (youngest child, often the youngest daughter), passage to a favored heir (usually a son), distribution among all sons or all daughters, or an even distribution among all heirs. In agricultural societies, land becomes the method of wealth transmission, while in stratified societies, inheritance will include titles, social status, and substantial wealth.

Heritable wealth, whether land, titles, or other forms will lead to specific inheritance patterns which are designed to secure the passage of wealth from one generation to the next. Inheritance laws will favor certain heirs over others creating inheritance patterns such as primogeniture, which was prevalent in Medieval Europe. In

historic European cultures, primogeniture secured the passage of titles, especially the throne, to the eldest male heir.

The transmission of heritable wealth fosters strict marriage patterns. Among stratified societies with large amounts of heritable wealth, individuals were required to make endogamous and/or isogamous marriages. By marrying within their own social group, it maintained the wealth or status of the group/family. Ultimately the desire to secure the transmission of wealth will lead to the creation of a closed social group and may ultimately lead to intermarriage among close relatives (e.g., uncle-niece marriage among the Spanish royal house in the fifteenth, sixteenth, and seventeenth centuries).

Boone (1986, 1988) found that high nobility sought endogamous and/or isogamous marriages for their firstborn sons, while lower status nobility often arranged endogamous hypergynous marriages for their daughters. By marrying their daughters up, possibly to the sons of the high nobility, they were able to bring additional power, prestige, and social connections to the family. Such marriages were made through political alliances and secured by substantial dowries.

Dickemann (1979) found that among the aristocracy of medieval Europe, eldest sons inherited their father's land, titles, wealth, and social status through primogeniture. This inheritance pattern also dictated that only sons were eligible to receive the greatest inheritance, the throne.

Primogeniture first appeared as an inheritance pattern during the reign of the Capetian (French) kings in the tenth century (Duby 1978). Prior to the tenth century, inheritance was often passed to a favored male heir who may or may not have been the firstborn. There were three types of potential heirs, children born into a marriage, adopted children, and illegitimate children born outside marriage. Children born to a marriage were the first to inherit followed by adopted children. Illegitimate children were not allowed to inherit family estates or principle titles, although they could inherit less important titles or wealth.

To secure the inheritance, and prevent in-fighting, only the eldest sons of the medieval French aristocracy were allowed to marry. Only in the event that an elder brother died without

marrying or leaving an heir would a younger son be allowed to marry. A slightly different pattern would develop in medieval England where all sons were allowed to marry, but only the eldest son was eligible to inherit the familial estate.

Conclusion

When resources are scarce, such as heritable wealth, distinct patterns for marriage and inheritance will develop, which are designed to maintain the financial standing and hierarchy within a family or social group.

Definition

A general definition of tool use describes the active manipulation of an external object to attain a goal.

Introduction

Fish, amphibians, and reptiles are frequently excluded from reviews of tool use (e.g., Bentley-Condit and Smith 2010) for a number of reasons including, first, the fact that there is a low expectation among cognitive scientists and comparative psychologists that these animals are clever enough to use tools and, second, that they are seldom observed with the same level of scrutiny afforded to primates and birds. Careful observations have, however, shown that there are examples of fish and reptiles using tools in the literature, though as yet there are no clearly documented examples for amphibians.

A Historical Perspective

Jane Goodall shocked the world when she first described tool use in primates in 1960 (Van Lawick-Goodall 1968). The idea that tools were solely the domain of *Homo sapiens* was firmly entrenched in both the philosophy and science of the day, beliefs that still color popular assumptions today (Ambrose 2001). Louis Leakey, anthropologist, famously responded to the news by saying “Now we must redefine tool, redefine man, or accept chimpanzees as human” (Peterson 2008). However, observations of tool use in fish had already been published 3 years prior to Goodall’s revelation, described without fanfare in a manual on the care of the brown hoplo catfish, *Hoplosternum thoracatum* (Bshary et al. 2002; Patton and Victoria 2015).

A number of factors lead to the decidedly differential response to tool use between the two species. At the time, it was astonishing enough that primates might use tools, let alone any other animal, so it is not surprising that observations of tool use in fish were overlooked. Still today, the

image of a cold-blooded, witless fish having little capacity for higher-order cognition is pervasive. Despite the fact that cognition is notably absent from any definition of tool use, the assumption that a measure of intelligence is required for the behavior has persisted. Nevertheless, examples of tool use in animals lie in the full spectrum of cognitive underpinnings, from deterministic patterns of response to stimuli through novel, flexible problem-solving (Patton and Victoria 2015; Brown 2011). Rather than decreasing the value of tool use as a method of understanding animal cognition and behavior, however, the breadth of this spectrum serves to create a valuable and complex arena in which to understand the process of problem-solving in animals in the context of their environment (Patton and Victoria 2015).

Early assumptions that tool use might only occur in a small group of primate or primate-like species resulted in an unintentional problem of definitions. The most widely adapted definition required that a tool be disassociated from the surrounding environment and held in some way by the user (Beck 1980). This causes the paradox that using a rock to crack a shell would be categorized as tool use, but cracking a shell against a rock would not. Beck later adapted the definition to include any circumstance where the user controlled the tool, though this amendment in turn inspired debate about what precisely “control” meant (Shumaker et al. 2011). These standard definitions are problematic for any species lacking grasping appendages. Additionally, the physics of mechanically operating objects in an aquatic environment is fundamentally different from the parameters in air (Brown 2011; Pasko 2010). In the viscous environment of water, especially areas prone to strong flow or current, it may be more appropriate to maintain primary “control” over the object of interest. As any scuba diver has experienced, a dropped object immediately runs the risk of floating away (Pasko 2010). Therefore, we turn to Goodall’s original definition – the use of an external object in the attainment of an immediate goal – as the most appropriate definition inclusive of variety in both physiology and habitat type (Brown 2011; Patton and Victoria 2015).

Today, we know that tool use is not only present but also remarkably widespread throughout the animal kingdom (Brown 2011; Shumaker et al. 2011). In addition to primates and fish, there is evidence of tool use in elephants (Hart et al. 2008), bears (Deecke 2012), sea otters, dolphins (Krützen et al. 2005), crows (Hunt and Gray 2003), mongooses (Müller 2009), octopuses (Finn et al. 2009), ants (Möglich and Alpert 1979), and wasps (Brockmann 1985), among other species (Patton and Victoria 2015).

Tool Use in Fish

Considering the logistical difficulties in conducting long, unobtrusive hours observing fish behavior due to the restricted overlap in our natural habitats, there is a surprisingly large and increasing volume of literature providing evidence of the varied nature of tool use in fish.

To return to the brown hoplo catfish that provides our first known example in fish, the tool in question was a leaf on which the catfish would glue its eggs. Then, if threatened for any reason, they grasp part of the leaf in their mouth and carry it in the manner of a tray to move the eggs to the safety. It is noteworthy that this behavior fits the strictest definition of control, as the tool is carried directly by the fish. Similarly, both male and female South American cichlids will pick up and “test” several leaves before one is selected. As with the hoplo catfish, they lay their eggs on the leaf and then pick up it up and move it to a more protected location when threatened (Keenleyside and Prince 1976).

Rock anvils are common tools utilized by a number of fish species in order to smash open sea urchins, clams, and other well-protected food items. In 1971, two species of wrasse (*Cheilinus trilobatus* and *Coris angulata*) were found to use rock anvils to smash open sea urchins. They would repeatedly return to a particular stone located inside their territory, indicating a preference in their choice of tool (Fricke 1971). The yellowhead wrasse (*Halichoeres garnoti*) has also been observed breaking scallops on a rock anvil (Coyer 1995). As underwater cameras

became more ubiquitous, compelling photographs and video evidence have grown, including photographs of a blackspot tuskfish (*Choerodon schoenleinii*) (Jones et al. 2011) and video footage of an orange-dotted tuskfish (*Choerodon anchorago*) (Bernardi 2011) using an underwater anvil in the wild. In captivity, the sixbar wrasse (*Thalassoma hardwicke*) kept in communal aquaria and fed with pellets too big to be ingested also used an anvil to smash food into more manageable pieces (Pasko 2010), indicating that this behavior is not limited to native habitats.

Dead coral has also been seen being used as an anvil. In 2016, an adult blue tuskfish (*Choerodon cyanodus*) was videoed dragging a juvenile green turtle (*Chelonia mydas*) with its mouth. Tuskfish are known to be a primary predator of turtles, but until this footage there had been no observations to indicate the method of predation. In this case, the tuskfish first used a rock as an anvil against which to hit the turtle, before shifting to a larger dead coral head for its anvil and successfully stunning the turtle (Harborne and Tholan 2016).

These anvil-using species fall under the family Labridae, which may suggest that anvil use is a deeply conserved ancestral behavior in this group (Harborne and Tholan 2016). However, Labridae also include species of cleaner fish known for complex cognitive capacity, so a measure of cognitive flexibility in this evolutionary branch of fish may have helped tool use to develop.

A particularly unique example of innovative tool use has been observed in farmed Atlantic cod (*Gadus morhua*) (Millot et al. 2013). These fish were provided with self-feeders that allowed the release of food pellets into the tanks by means of a pulley. Activating the pulley required the fish to bite the string and swim forward and then release it and swim to the area the food was released. In these tanks, individual cod were identified by means of a beaded tag located by the dorsal fin. In two separate tanks, fish accidentally entangled then disentangled their bead with the pulley mechanism, in the process triggering the feeder to release pellets. After these initial accidental interactions, three fish spread across the two tanks learned to hook their bead in the trigger mechanism to activate the feeder. Analysis of the

movement shows that the series of actions were both coordinated and fine-tuned over more than 100 repetitions of the behavior across each fish. Using the tag to trigger the device was advantageous because the fish was able to rapidly catch the pulley, swing around, and end immediately by the food outlet instead of having to mouth the pulley, let it go, and then turn and swim back to the food. The speed at which the fish was able to return to the outlet when using the tag to trigger the device allowed them to beat their competitors to the food source (Millot et al. 2013).

It cannot be overlooked that water itself can be used as a tool, even in an aquatic environment. A further method of overcoming the defenses of sea urchins (clearly a common problem among many fishes) is displayed by the rippled triggerfish (*Balistes fuscus*). By blowing a stream of water directly under sea urchins to dislodge them from the rock, they expose the less-spiny underside of the urchin. The fish can then bite the oral disc, the weakest and least defended part of an urchin. In an experimental setting, it also was determined that the fish would only select smaller urchins, as the larger, heavier specimens were generally unmoved by the strategy. A different approach is employed by the orange-lined triggerfish (*Balistapus undulatus*); here, the fish breaks off the sea urchin spines one by one until the urchin can be grasped and lifted into the water column. After swimming upward a certain distance, the fish then drops the urchin. As it drifts downward, the triggerfish swims under the urchin and bites it from the undefended angles (Fricke 1971).

Water is used ballistically by fish as well. Archerfish (*Toxotes* sp.) are opportunistic hunters that use a specialized groove in their mouth to precisely shoot jets of water at aerial prey (Schuster 2007). Almost all aspects of the archerfish's hunting skills are learned (Schuster et al. 2004; Schuster 2007, 2010; Schlegel et al. 2006), and young archerfish will learn both by practice and by observing the action of more skilled archers. In aiming, the fish cope with refraction at the air–water interface (Schuster et al. 2004), discern camouflaged targets against complex backgrounds (Schuster 2007), and estimate both distances and speed of targets to

successfully knock down prey with their shot (Schuster et al. 2006; Schuster 2010).

It is becoming increasingly clear that, despite the early assumptions in the field, it is not at all uncommon for fish to manipulate external materials available to them in order to accomplish a task. Though the underlying cognitive capacity may vary from basic to complex, there is good evidence that indicate that higher-order cognitive processing can be involved.

Tool Use in Reptiles

Use of objects as hunting lures is rare among animals, with examples found in capuchin monkeys, a few bird species, and one insect (Shumaker et al. 2011). Dinets and collaborators (2015), however, recently reported the use of small twigs and sticks as bird lures by two species of crocodilians (*Crocodylus palustris* and *Alligator mississippiensis*). Both species live in ponds where some birds species, and particularly egrets (*Egretta garzetta*), nest in trees. The crocodilians appear to deliver protection against tree-climbing nest predators such as snakes, monkeys, and raccoons; however, the birds pay a direct cost for this protection when chicks that accidentally fall into the water are snatched up and consumed by waiting crocodilians (Dinets et al. 2015). On the whole, the protection seems to be worth the cost, and many crocodile farms and alligator parks are often found alongside egret rookeries when appropriate egret-nesting trees are in the area.

In 2007, while studying the behavior of mugger crocodiles (*C. palustris*) in large ponds where the rookery trees were growing, Dinets and colleagues repeatedly observed large muggers lying in the shallow water along the edge of the pond with small sticks and twigs positioned across their snouts. The crocodilians remained perfectly still for hours, and if they did move to change position, they did so in such a way that the sticks remained balanced on their snouts. The behavior potentially fooled nest-building birds wading in the water for sticks, and when birds approached and stretched their necks toward the stick, the crocodilians lunged at the bird.

To see if the stick was intentionally positioned on the snout, Dinets and his colleagues performed systematic observations of alligators for 1 year at four sites in Louisiana, including two rookery and two non-rookery sites. The researchers observed a significant increase in alligators displaying sticks on their snouts from March to May, the time when birds build nests for breeding. Specifically, the reptiles in rookeries were observed with sticks on their snouts during and after the nest-building season. At non-rookery sites, the reptiles used lures during the nest-building season. The research by Dinets and colleagues is the first report of tool use by any reptiles and also the first known case of predators timing the use of lures to a seasonal behavior of the prey.

It is unknown what factors stimulate stick-displaying behavior at particular locations and at a particular time of year. The predators might be reacting to different environmental cues such as the presence of large numbers of wading birds flying over the water or the sounds made by the courting birds. It is also unknown to what extent stick displaying by crocodilians is produced by individual insights, cultural transmission, and/or previously evolved instinct.

Regardless of what underlies these observations, however, the historic view of crocodilians as lethargic, slow, and boring is challenged by the fact that these animals exhibit flexible, multi-modal signaling, advanced parental care, and highly coordinated group hunting tactics (Doody et al. 2013). These discoveries are particularly interesting because they could suggest that tool use behavior will be more widespread within the reptilian group.

Tool Use in Amphibians

Currently, there is no record of tool use in amphibians (Shumaker et al. 2011). The fact that there is no publication on this topic does not mean that amphibians are not able to use tools; it seems more likely that it simply has not been expected and so has not been explicitly searched for. However, given observations of tool use in both fish and reptiles, it is reasonable to conclude that there

may be examples of amphibians using tools eventually reported.

Conclusion

A small change in the common definition of tool use – the requirement a tool must be held to be employed – allows the enormous variety in both physiology and environment that animals possess to be taken appropriately into account. This has released fish from an obvious anatomical constraint and allowed a remarkable number of examples of tool use in fish to be correctly categorized. As both technique and technology allow our capacity to conduct long-term studies of in situ fish behavior to dramatically expand, we expect there will be more examples of unique behavior to be recorded. In reptiles there is just one recent report of tool use, and examples are still lacking for amphibians. The paucity of literature for these latter taxonomic groups is most likely due to the difficulties of making behavioral observations in their natural environment and may also be because amphibians and reptiles are often considered to have limited cognitive capacities that may not support innovation and tool use. Nonetheless, reports of tool use in both fish and crocodilians are significant because they suggest tool use has a much longer evolutionary history than has been previously recognized.

Fisher's Reproductive Value

Andy Gardner

School of Biology, University of St Andrews,
St Andrews, UK

Definition

The expected contribution of genes made by an individual or class to generations in the distant future.

Natural selection is driven by differences in individual reproductive success, but a simple count of the number of children that individuals produce is often insufficient to describe their Darwinian fitness. For example, in a well-mixed population with a female-biased sex ratio, a mother who produces only sons will tend to have more grandchildren than will a mother who instead produces an equal number of daughters. And simply counting the number of grandchildren may also be insufficient, as these too may differ in their quality in terms of how many children they will have. R. A. Fisher's theory of reproductive value resolves this conundrum by defining the fitness of individuals – or whole classes of individuals – in terms of their expected contribution of genes to generations in the distant future. This concept has broad application within Darwinian evolution and is particularly crucial for the understanding of social evolution.

An individual's reproductive value can be defined recursively, in terms of her share (typically one half, in a diploid population) of her children's aggregate reproductive value, with each child's reproductive value being their own share of their own children's aggregate reproductive value, and so on. Although this might appear to lead to an unresolvable infinite regress, reproductive value can be readily calculating using elementary linear algebra. Indeed, the mathematics of reproductive value directly mirrors that of Google's hugely successful *PageRank* algorithm, which quantifies the importance of a webpage on the Internet according to the aggregate importance of all the webpages that link to it (Fig. 1). Whereas

PageRank is the relative probability that an Internet surfer who clicks on links entirely at random will, after some large amount of time, find themselves browsing a particular webpage, reproductive value is the relative probability that a gene chosen at random from the distant future will trace its ancestry to a particular individual or class in the present generation.

Fisher first introduced the concept of reproductive value in relation to age-structured populations, in the prelude to his derivation of the "fundamental theorem of natural selection" (Fisher 1930). The problem here is that while Fisher defined natural selection in terms of systematic change in the genetic constitution of a population, there are systematic changes associated with other factors, such as age. For instance, a neutral allele that is found only in post-reproductive individuals will inexorably decline in its per capita frequency until it is lost from the population, not through the action of natural selection but rather on account of that age class leaving no descendants. Accordingly, Fisher corrected for such class effects by defining the population frequency of an allele as a weighted sum of its frequencies within each of the age classes, with the class reproductive values providing the weights. This recovered Darwin's (1859) stipulation that natural selection increases the frequency of beneficial variants, decreases the frequency of deleterious variants, and does not alter the frequency of neutral variants.

In the context of his treatment of age structure, Fisher (1930) made some cryptic remarks as to the potential for natural selection to have molded the relationship between age and incidence of natural death, on account of it having greater power to improve survival at those ages at which reproductive value is greater. Fisher appears to have mistakenly focused on the reproductive value of the individual, rather than the whole age class, but this was rectified by Peter Medawar (1952), who developed the idea into a fuller evolutionary theory of senescence. Medawar's account emphasized the tension between natural selection and recurrent deleterious mutation, with the decline of class reproductive value with age weakening natural selection's ability to purge the population

F

Fisher's Reproductive Value, Fig. 1 Fisher's reproductive value and Google's *PageRank*. (a) Offspring number is not a good measure of Darwinian fitness, because offspring can vary in quality. Reproductive value provides a better measure, because it also describes the success of these offspring, the success of their offspring, and so on down the generations. The yellow individual has only two offspring, but these are of high quality, each leaving two offspring of their own. The blue individual has three offspring, but these are of low quality, leaving one offspring each. Calculation of reproductive value requires that we know how successful these grandoffspring will be but, all else being equal, the yellow individual has the highest reproductive value, as she leaves the most descendants. (b) The number of links pointing to a webpage is not a good measure of that webpage's

importance, because linking webpages can vary in their own importance. Google's *PageRank* – so-called because it was developed by Larry Page, rather than because it ranks webpages per se – provides a better measure of importance, because it also describes how many links point to these linking webpages and so on through the whole of the Internet. The yellow webpage is only linked twice, but these are from important webpages that are also linked twice. The blue webpage is linked three times, but these are from unimportant webpages, each linked only once. Calculation of *PageRank* requires that we know how the whole Internet is linked together (see Page et al. 1999 for details) but, all else being equal, the yellow webpage has the highest *PageRank*, as it is altogether more linked to by the rest of the Internet

of mutations contributing to death in older age. Medawar also suggested that genes responsible for senescence might actually be favored by natural selection, on account of possible pleiotropic increases in fertility manifesting earlier in life, with the decrease in class reproductive value with age making the fertility of the young relatively more evolutionarily important than the survival of the old.

Fisher (1930) next used the notion of reproductive value to great effect in explaining why there is usually equal investment of parental resources into sons and daughters, building and improving

upon arguments put forward by Charles Darwin and Carl Düsing (West 2009). On account of the total reproductive value of all newborn females being equal to that of all newborn males then, in the event of any population imbalance in the investment into females versus males, a unit of parental investment into the underinvested sex will on average yield a higher return of reproductive value. Accordingly, Fisher argued that natural selection favors those parents who act to correct any imbalance in the population's sex allocation and will thereby restore the equal investment into sons versus daughters. This "rarer-sex effect" lies

at the heart of a very large body of theoretical and empirical work on sex allocation (West 2009).

The application of reproductive value to sex allocation illustrates how it provides not only a measure of how different individuals are differently valued by natural selection but also how they are differently valued by each other. On account of reproductive value considerations, a mother is favored to invest more heavily into sons than daughters when males are the rarer sex. Another factor that influences the valuation that one individual places on another is their degree of genetic relatedness, which is central to the theory of kin selection. Hamilton (1972) first incorporated the mathematics of reproductive value into kin selection theory to illuminate the biology of social insects, whose colonies exhibit age, sex, caste, and ploidy forms of class structure, and the modern theory of kin selection puts relatedness and reproductive value on equal conceptual footing, recognizing both as fundamental measures of value (Frank 1998). This development has been essential in moving the explanatory domain of formal kin selection theory beyond simple interactions between generic, interchangeable individuals and enabling its application to real-world biological systems in all their complexity.

The other major approach to social evolution is the group selection or multilevel selection approach. In contrast to what has been done in relation to kin selection, there has been very little interest in reproductive value in the context of multilevel selection. Yet the concept of reproductive value resolves several of the conundrums that plague that literature (Gardner 2015). For example, a long-standing dispute concerns whether it is better to conceive of a group's fitness being equal to the number of daughter individuals it produces (the "collective fitness 1" approach) versus the number of daughter groups it produces (the "collective fitness 2" approach), with this decision leading to different fitness estimates when daughter groups can contain different numbers of daughter individuals, and hence ambiguity as to how group selection is supposed to operate and what phenotypes it actually favors (Okasha 2006). The theory of reproductive value provides a resolution, by recasting the fitness of the group as its

expected genetic contribution to the distant future – which can be alternatively viewed as its share of the aggregate of the reproductive values of its daughter individuals or daughter groups, with both aggregates yielding the same total reproductive value (Gardner 2015).

Conclusion

Fisher's notion of reproductive value is a fundamental concept in the study of Darwinian adaptation and is of particular importance to the study of social evolution in which fitness consequences of social behaviors for multiple parties must be rendered in the same universal currency if they are to be properly understood.

Definition

Fisherian runaway selection refers to the theory first proposed by R.A. Fisher (1930) that the exaggerated secondary sexual characteristics of animals could evolve by means of a runaway evolutionary process in which an initial small adaptive dimorphism was then further developed into a much more heightened trait by an ongoing

interactive combination of female selective choice and increased male advantage.

Darwin on Sexual Selection

Charles Darwin had first posited the existence of two distinct principles involved in sexual selection (Darwin 1874 [1871]). The first was the “law of battle,” or males combating each other for access to females (intrasexual selection), and the second was female choice (intersexual selection), or females selecting which of the surviving males they elected to mate with (Fisher 1930, p. 131). Across the first few decades of work on evolution after Darwin, it was generally the case that the “law of battle” principle was accepted much more than the principle of female choice.

Darwin had certainly attributed the ability to discern beauty to females, both animal and human, explaining that:

When we behold a male bird elaborately displaying his graceful plumes or splendid colours before the females ... it is impossible to doubt that she admires the beauty of her male partner. As women everywhere deck themselves with these plumes, the beauty of such ornaments cannot be disputed. (Darwin 1874 [1871], p. 92)

By implication, Darwin was asserting that female birds and female human beings share a common aesthetic judgment, at least in relation to evaluating bird plumage. However, opposition to the idea of female choice was asserted by A.R. Wallace, the co-originator of the idea of evolution by natural selection, who asserted that it was “almost inconceivable that female preference could have been effective in the way suggested” by Darwin (Wallace 1889, p. 295). Wallace’s opposition to female choice was important in that many later contributors to the theory of evolution took their impetus on this topic from Wallace rather than Darwin.

Fisher on Runaway Selection

One of the few early twentieth-century contributors who took their impetus on sexual selection directly from Darwin was Ronald Fisher. He

developed Darwin's theory by proposing that male selective advantage, and the associated female choice for this advantage could, in certain instances, mutually reinforce each other in a runaway process, or a positive feedback loop (Prum 2017, p. 37), that served to develop the male trait and its correlated desirability in females to an exaggerated degree. As Fisher explained:

In such cases the modification . . . proceeds under two selective influences (i) an initial advantage not due to sexual preference . . . and (ii) an additional advantage conferred by female preference . . . The importance of this situation lies in the fact that the further development of the . . . character will still proceed, by reason of the advantage gained in sexual selection, even after it has passed the point in development at which its advantage in Natural Selection has ceased . . . There is thus in any bionomic situation, in which sexual selection is capable for conferring a great reproductive advantage, the potentiality of a runaway process, which, however small the beginnings from which it arose, must, unless checked, produce great effects, and in the later stages with great rapidity. (Fisher 1930, pp. 136–137)

This runaway selection process, after being first initiated, would eventually encounter some natural checks that would end it. For example, if the disadvantage to the males of their exaggerated sexual ornaments so diminished the number of survivors in the breeding season that counterselection occurred in favor of less ornamented males, then the runaway process would end.

Fisher hypothesized that runaway selection most likely occurred in sudden spurts of change that were brought to a swift halt by such counterselection tendencies. Examples that he discussed were *Homo* traits for heroism, valor, and public spiritedness, which he implied had been subject to sexual selection pressure as exerted by tribal opinion (Fisher 1930, p. 247). One more general innovation pointed out by Fisher was that an organism's reproductive success was measured not simply by the number of its own offspring, but also the likely success of these offspring in having offspring themselves (Fisher 1930, p. 143). Another key aspect of Fisher's account was that it was clearly specified that animal traits could evolve that diminished survival

advantage, but heightened the capacity of females to discriminate aesthetic qualities (Milam 2010, p. 46).

Fisher's book was first published in 1930, when there were still some significant doubts being expressed about the idea of female choice, as was initiated by Wallace, even though a few others had supported it, so Fisherian runaway selection was not immediately taken up and lauded as the more sophisticated theory that it was.

Runaway Selection After Fisher

It was not until the early 1970s, and the publication of a volume devoted to the topic (Campbell 1972), that sexual selection was fully reinstated as a key component of the theory of evolution as Darwin had intended it to be. This volume briefly considered Fisher's runaway idea that "controlling female preference and advantageous male characters should evolve with extreme rapidity" (Selander 1972, p. 219). New impetus to Fisher's work on runaway selection then occurred in the contributions of Peter O'Donald (1980), Russell Lande (1980), and Mark Kirkpatrick (1982), each of whom developed a more sophisticated version of Fisher's initial idea.

O'Donald added the idea that "females will respond to the more extreme males as to a 'supernormal stimulus' and prefer them to the others" (O'Donald 1980, p. x), as a means of explaining why females would select for the more extreme versions of particular traits. Kirkpatrick concluded that "the initial selective advantages for the female preference . . . are not necessary for either the origin or subsequent elaboration of mating preferences for traits associated with reduced survivorship" (Kirkpatrick 1982, p. 1), as the advantage of having sexually attractive offspring by itself was sufficient: Fisher's sexy son hypothesis. Two approaches to the female choice component of runaway selection have subsequently emerged, relative and absolute preference. In the latter, females have an innate preference for a specific degree of dimorphism, whereas in the former, they have only a relative preference for

bigger/brighter is better (Gould and Gould 1997, p. 183).

In order to better understand the interaction between natural selection and sexual selection processes in generating trait evolution, both Lande and Kirkpatrick designed mathematical models of the coevolutionary dynamics between display trait development and mate choice criteria. Together they showed that:

... natural and sexual selection on display traits will establish a balance between the two opposing forces. At this equilibrium, the male may still be quite far from the natural selection optimum, but that's the cost of doing business with sexually autonomous, choosy females ... this balance between natural and sexual selection is not restricted to a single point. Rather, there exists a line of equilibrium – literally, an infinite number of possible stable points of balance between natural and sexual selection on a given display trait ... the further away a display trait is from the natural selection optimum, the stronger the sexual advantage must be for it to evolve. (Prum 2017, pp. 42–43)

In addition, it was pointed out that elaborate physical ornaments are subject to random mutation, but that these mutations are more likely to make the ornament less elaborate rather than more elaborate. This mutational bias toward lesser ornamentation showed that it was definitely worthwhile for females to select the most ornamented males (Ridley 1994, p. 140).

More recently, it has been suggested that mate preferences may in certain instances evolve cyclically, or through successive runaway periods, instead of toward a stable long-run equilibrium. If small differences in risk factors exist between different populations, cyclic evolution among species can lead to divergence and to sexual isolation (Pomiankowski and Iwasa 1998). This is part of the larger topic of the role of sexual selection in sympatric speciation.

In addition, the recent tendency in the developed world for parents to favor super-high levels of investment in a very small number of children has been analyzed as a form of runaway parental investment (Mace 2007, p. 393). Also, it has been suggested that runaway selection can occur even in the absence of a correlation between male traits and female preferences, as social influences on

mate evaluation can facilitate its initiation (Bailey and Moore 2012). And in opposition to runaway selection, the related process of chase-away sexual selection has been outlined. This involves antagonistic coevolution where the female develops an aversion to the evolving male trait, which in turn causes the trait to become more pronounced as a means of overcoming the female aversion (Holland and Rice 1998).

Finally, in economics the concept of runaway capitalism has been proposed as a way of understanding the problematic evolution of some companies. Single-measure company success criteria often begin as being valid but over-reliance on them can lead to a runaway process in which the single measure becomes both more significant, but also increasingly out-of-touch with overall company performance (Meyer and Kirby 2012, p. 68; Giddens 2002; Miller 2007).

Sexual Selection and Evolutionary Psychology

It is worth briefly considering Fisherian runaway in relation to the psychological mechanisms that have been proposed in evolutionary psychology. As has rightly been explained, “Sexual selection ... is concerned not merely with the evolution of the physical characters of the body, but also, and no less, with the psychological attributes thereof” (Pycraft 1913, p. 18). Therefore, by extension, some of the psychological attributes of animals have been subject to runaway sexual selection pressures, just as some of the physical attributes have been, perhaps producing exaggerated *Homo* traits such as high intelligence and the runaway brain. Runaway brain evolution has progressed so far in human beings that most brain size growth now occurs after birth, an unusual phenomenon (Wills 1995, p. 6).

Moreover, if in the literature on evolutionary psychology it is accepted that there are sex differences in cognition (see Puts et al. 2007), then one component part of these sex differences must be sex differences in aesthetic cognition (or aesthetic dimorphism), i.e., sex differences in conceptions of beauty. This would not necessarily mean that

aesthetic cognition was in all respects different in males and females, only that some aspects of it would vary between the sexes. This aesthetic dimorphism is related to (but is not identical with) sex differences in evaluating the various different features of mate value.

It can further be hypothesized in this respect that, as the degree of sexual dimorphism exhibited in a given species increases, the associated sex differences in aesthetic cognition might also increase. This aesthetic dimorphism will most likely be contained as sexual dimorphism in the psychological mechanisms that are associated with artistic evaluations. For example, on average over large numbers of individuals, men prefer women shorter than themselves whereas women prefer men taller than themselves, despite the fact that tall women have a reproductive advantage: larger pelvises facilitate less problematic births (Touraille 2015, p. 515). Consequently, aesthetic categories may well be in operation in promoting such sexual selection judgments.

Returning to Fisher's work, he outlined a speculative theory as to the origin of all aesthetic criteria as follows: "there can, I think, be little doubt that it [the aesthetic category of evaluation] arose as an intellectual synthesis of the innumerable points, each a factor of sexual preference, which an enlarging intelligence would learn to harmonise" (Fisher 1915, p. 188). Thus, the ultimate foundation of all aesthetic judgment was a synthesis of the evolved psychological mechanisms of sexual attraction.

Conclusion

The contentious status of sexual selection as part of the wider theory of evolution has waxed and waned ever since Darwin first developed the idea (1874 [1871]); similarly, the status of Fisherian runaway selection – and associated female aesthetic capacity – has also varied over time. Its main recent competitors have been, first, the Zahavi handicap principle (1975), which asserts that female choice criteria are linked to fitness-exhibiting traits ("good genes"), or the ability of males to function successfully while carrying

physical incapacities (or handicaps), rather than the purely aesthetic criteria of beauty, and, second, truth in advertising or that costly handicaps directly assist survival (Kodric-Brown and Brown 1984). Opponents of runaway selection also posit that the costs associated with the time-consuming process of mate choice mean that there must be some fitness benefits to ornaments.

Some recent research has suggested that, in fact, both runaway selection/aesthetic capacity and the handicap principle may apply, but to different types of animals. Animals with only a single main ornamental feature obey the fitness-indicating handicap principle, whereas animals with multiple different ornaments employ purely arbitrary aesthetic criteria (Ridley 1994, p. 148). In addition, it is possible that the initial form of an ornament may evolve for fitness-enhancing reasons, then runaway selection may assume control, but as the exaggerated trait becomes ever more costly to maintain, only the strongest and healthiest individuals will be able to cope, thereby ultimately producing an honest signal of overall fitness.

It is also necessary to point out that "mate choice" is often a complex process with many different factors being involved, such as individuals attempting to interfere in mating behaviors, being subject to predator dangers, employing multiple substitutable attraction criteria, evoking prior experiences, being embedded in nested levels of competition, being subject to the effects of mating hotspots, and attempted association with dominant "hotshot" males (Gibson 2002, p. 614).

Finally, it is worth noting that Fisher's first article on the topic of sexual selection began by making the assertion that, of all the branches of biological science, "few, if any, are as attractive as the subject of Sexual Selection" (Fisher 1915, p. 184), implying that Fisher had selected this topic to investigate because of its intrinsic beauty, further reinforcing the importance of attraction criteria to varied forms of animal behavior (Miller 2002).

Fitness Benefits of Costly Signalling

Reproductive value

Definition

Signals convey information between living organisms. Sexual signals advertise genetic quality and may serve to enhance the reproductive fitness of the signaller. The high costs associated with such signals serve to maintain their integrity.

Introduction

Signalling theory is an area of evolutionary biology concerned, in part, with communication between individual living organisms. This field of research has received considerable attention, and signals may broadly be considered in two categories (Nur and Hasson 1984). The “Additive Model” concerns signals aiming to deter an opponent, such as that from prey to predator. During a chase, gazelles (*Gazella* sp.) may communicate fitness and speed by “slotting” or vertically jumping, when fleeing a predator. On first appearance, this may seem energetically wasteful, because the energy involved in jumping could be otherwise directed toward escaping. However, the communicated message of speed and agility may discourage the predator from the pursuit, thereby facilitating the gazelle’s escape. In addition to deterring an opponent, signalling is also used to promote sexual fitness. The second category, the “Multiplicative Model,” considers signalling of a sexual nature, which endeavors to communicate value as a prospective mate. Investment in such signals may enhance mating success by communicating underlying genetic and reproductive quality, which might otherwise be unobservable. It is this form of signalling in humans that will be the focus of this entry. The mechanisms acting to maintain signal integrity will also be discussed.

Maintaining Signal Integrity

This system of communicative signalling between individuals can only operate effectively if signal integrity is assured. However, individuals would benefit from the ability to deceive others through dishonest signalling, which would allow for a

false portrayal of their genetic and reproductive quality. Such dishonest signalling may serve to deter a predator or to attract a potential mate. Although natural occurring dishonest signalling is difficult to demonstrate, recent observations of claw size in male fiddler crabs (*Uca annulipes*) suggest that cheating may be common and undetectable (Backwell et al. 2000).

The handicap hypothesis (Zahavi 1975) was proposed to explain how evolution might lead to reliable signalling between individuals, despite the powerful motivation for duplicitous communication. The handicap hypothesis suggests that for a signal of quality to be reliable and honest, it must be costly to the signaller.

This principle is exemplified by sexual signalling in male deer (Cervidae), who grow new antlers each year. While antlers enhance fighting ability and therefore boost mating success, they require massive energetic investment in growth and impede the deer when escaping predators. Antlers therefore enhance reproductive success while concurrently decreasing fitness in other ways. Only male deer with high levels of fitness to begin with are able to afford to reduce their fitness and still survive by growing large antlers. An individual of lower genetic quality would therefore be unable to mimic the signal, ensuring that the integrity of the signal is maintained (Sugiyama 2015). The inherent principle is that any costly signal will serve as a reliable indicator of reproductive quality and be attractive to the opposite sex (Graffen 1990; Zahavi 1975).

Signalling in Humans

The cues which attract men to women and vice versa have been the subject of much research interest. The evolutionary importance of sexual signals stems from individual variability in heritable fitness, with the result that those who reproduce with an individual of high heritable fitness will gain a fitness benefit relative to those who do not. As underlying genetic quality cannot be observed directly, the ability to both signal and perceive cues of genetic quality evolved through intersexual selection.

Although there are similarities between the sexes with respect to which traits are deemed desirable in a partner, there are also well-documented differences. The psychological mechanisms underpinning judgements of attractiveness in the opposite sex are considered to be evolutionary adaptations serving to promote one's own genetic survival through successful reproduction (Thornhill and Gangestad 1999). This section will go on to discuss the underlying qualities sought in a mate by both men and women and provide examples of how such characteristics may be signalled.

Female Signalling

Female cues of beauty are thought to signal general health, reproductive potential (a measure of future reproductive potential, strongly linked to youth), and current fertility (i.e., hormonal profile) (Sugiyama 2015). Such cues positively correlate; women with attractive faces also have attractive figures, body odors, and voices (Feinberg et al. 2005). The ability to communicate underlying reproductive quality is evolutionarily important as fertility may vary considerably between women. General health is valuable in a female partner because it not only predicts fertility but also demonstrates ability to provide quality care for offspring and to pass on healthy genes. Consequently, as age and health are major indicators of reproductive potential, attractiveness is also often linked to visual cues communicating youthfulness and vigor.

Hair is a putative signal of youth (and therefore reproductive potential) and health. Age is communicated through color (although this can now be manipulated), and hair may signal health through a shiny and strong appearance. In contrast, illness may damage hair, and full-term pregnancy may cause coarseness or brittleness, potentially allowing women who have borne children to be distinguishable from those who have not (see Hinsz et al. 2001).

Pitch of voice and facial femininity may also be indicative of mate quality. The two cues positively correlate, and males find the faces of

women with high-pitched voices more attractive than those of women with low-pitched voices (Feinberg et al. 2005). This male preference for feminine faces and voice may be adaptive, as both associate positively with reproductive development and health via elevated estrogen and decreased testosterone. Both signals may thus be communicating the same underlying qualities of hormonal status and reproductive health. Furthermore, the attractiveness of female faces (Roberts et al. 2004), voices (Pipitone and Gallup 2008), and body scent (Gildersleeve et al. 2012) varies across the menstrual cycle, increasing during the fertile phase. This may lead to reproductive benefits for females by being better able to attract mates at a time when conception is most likely (see Welling and Puts 2014).

Populations do not exist in isolation of their environment; the dynamic nature of energy availability influences signals of mate quality. The significant energetic burden of pregnancy and lactation makes a reproducing female vulnerable to food insecurity. Due to the historical (and, to a lesser extent, contemporary) prominence of this challenge, female reproductive robusticity may be enhanced, and signalled, by fat storage. The anatomical distribution of fat stores is linked to the onset of pubertal endocrinological activity and has implications for reproductive potential. The most significant, and observable, distribution pattern is the relative adiposity of the waist and the hip (the waist to hip ratio, WHR). Low ratios (i.e., large hips in relation to waist) are linked with greater current fertility and are deemed more attractive as a reproductive partner. In addition to being linked to fertility, WHR is a predictor of health and therefore of potential to provide parental care and contribute healthy genes to the next generation. As with facial attractiveness, WHR varies by menstrual cycle stage, reaching a low point during ovulation. In this way, WHR may act as a signal of when a woman has reached peak fertility (see Confer et al. 2010; Welling and Puts 2014).

The female face and the body may convey different cues concerning health and fertility. Faces are thought to reflect youth and health and hence provide information about reproductive

potential. In contrast, women's bodies reflect current fertility. Men may exhibit a condition-dependent adaptive propensity to prioritize bodily cues of attractiveness when assessing a potential short-term partner and facial cues for potential long-term partners. This is thought to be because current fertility is more pertinent than future reproductive potential in a short-term mate (Confer et al. 2010). Although individual males naturally differ in the extent to which they may pursue one mating strategy over another, situational factors such as an increase in relative status or mate value following sporting competition may cause a shift toward a short-term approach in order to capitalize on reproductive opportunities (Longman et al. 2018).

Male Signalling

Human males may signal mate value by demonstrating ability to provide ongoing care and resources, as well as through physiological cues pertaining to genetic quality. The high value placed by females on male ability to acquire resources has been well documented (Buss 1989). This is evident in pre-industrial human societies, where males exhibit a positive relationship between status and number of surviving offspring. Prior to agriculture, hunting may have represented an important means by which male resourcefulness could be demonstrated. Food is inexorably linked to status in many cultures around the world, and there is evidence that superior hunters enjoy not only social prestige within the community (Altman and Peterson 1988) but also enhanced reproductive success (Hill and Kaplan 1993; Kaplan and Hill 1985). Hunting may therefore be motivated by male-male competition (Hawkes et al. 2001). Recent research suggests that hunting ability might act as a reliable signal of male fitness by demonstrating ability to acquire resources, in addition to its function of calorie acquisition (see Longman et al. 2015).

The same may be true of contemporary Western society. Both anthropologists and historians have argued that an integral characteristic of human societies is that men seek to acquire wealth

and status, with the aim of converting such gains into reproductive success (see Nettle and Pollet 2008). Today, increasing male income has been shown to have a significant effect on male reproductive success and desirability as a marriage partner (Hopcroft 2006). This appears to be consistent across a range of cultures, suggesting that selection for male wealth will exist wherever there are accumulable resources. It is worth noting that various studies have failed to observe positive relationships between male socioeconomic status and reproductive success but that it has been argued that these studies have inherent methodological and conceptual problems (see Nettle and Pollet 2008).

Thorstein Veblen, a Norwegian-American economist and sociologist, coined the term "conspicuous consumption" to describe the act of spending money on acquiring expensive goods and services in order to publically communicate wealth or status (Veblen 1899). Although such spending may be perceived as being wasteful, the observation that it seems to be a consistent feature spanning history and culture suggests an evolved explanation, one aimed at signalling wealth and converting this into reproductive advantages. Such spending may be concerned not only with displaying economic resources, but rather it signals a specific, short-term mating strategy, and women perceive this as such (see Sundie et al. 2011).

Male physical cues, in addition to the behavioral cues previously discussed, may also play an important role in communicating desirability as a sexual partner. As previously stated, a man's value as a mate depends on both his ability and willingness to provide paternal care and support, as well as his heritable fitness (Gangestad and Simpson 2000). While both aspects of mate value are important when selecting a long-term partner, a man's value as a short-term mate depends heavily on his heritable fitness. A range of studies have demonstrated that women's mate preference depends upon whether a short-term or a long-term partner is desired (see Gangestad et al. 2007) and is influenced by menstrual cycle phase. The role of male masculinity in mediating these preferences is an active area of research interest.

Male masculinity is considered an honest signal of genetic quality. As previously discussed, in order for a signal to be honest and reliable, it must be costly to the signaller. Masculinity is indicative of androgenization, which comes with a fitness cost due to the immunosuppressive effects of testosterone (the “Immunocompetence handicap hypothesis,” Folstad and Karter 1992). High levels of testosterone are also linked to increased incidence of prostate cancer, oxygen radical production, reduced tissue and organ maintenance, injury associated with aggressive confrontational behavior, and suppression of innate immune function (Lassek and Gaulin 2009; Muehlenbein 2006). Masculinity may be conferred through facial structure, as well as through muscularity. In addition to the aforementioned costs of androgenization, muscularity imposes a significant metabolic burden due to the high energy demands of muscle tissue (Elias 1992). While both traits have been proposed to be a positive cue of genetic and therefore heritable quality, both may also serve as negative cues of paternal investment.

Women’s preference for masculine traits is understood to vary with probability of conception. During the follicular (fertile) phase of the menstrual cycle, women may be more attracted to more masculine facial features, muscularity, and scent (a correlate of bilateral symmetry and hence developmental stability). These shifts in preference occur only when ovulating women are considering a man as a short-term partner. As masculine traits infer genetic quality, the timing of such preference changes may be adaptive in that they promote the acquisition of high-quality genetic material at a time when conception is most likely to occur (see Frederick and Haselton 2007; Gildersleeve et al. 2014; Jones et al. 2008).

Summary

Signalling is used to communicate underlying characteristics that may otherwise be unobservable. The integrity of such signals is maintained due to the high cost of the signal itself. Adaptive mechanisms have evolved to both

confer and perceive traits that may enhance one’s own fitness.

Fitness Benefits of Mate Guarding for Males

Emma I. Fullerton

Western Illinois University, Macomb, IL, USA

Definitions

Evolutionarily stable strategy: An evolutionary game theory that helps create a framework of the differential success of cooperating and defecting strategies, culminating in an equal payoff for players the majority of the time (Ray-Mukherjee 2016).

Mate guarding: Is the act of males spending time with females pre- or post-copulation, longer than is required for fertilization, in order to reduce sperm competition (Chaudhary and Geethanjali Mishra 2017).

Free-riding competitors: A competitor who chooses to not cooperate in collective action situations, thereby not incurring costs but receiving benefits from others' action. Also known as the prisoner's dilemma (Molander 1992).

Introduction

Many biologists and anthropologists study mating strategies to better understand different methods of passing on genetic material. Across species, males and females exhibit differing

bonds (pair-bonds, extra-pair copulations, promiscuity), different ratios of resources devoted to mate competition (aggressive displays, physical competition, mate guarding), and differing levels of care for offspring (female-only caregiving or male and female sharing caregiving responsibilities).

Fitness Benefits

To model offspring production, Hawkes et al. (1995) reduces the complexity of parental strategies by focusing on three main male strategies of optimizing paternity. The studied male strategies consist of contending for mating opportunities, guarding his current mate from other males, and caring for his offspring. This means models ignore the powerful effects of female choice, these models are also simplified by setting competition, guarding, and care as mutually exclusive, and ignoring temporal restraints.

A robust outcome is that males focus their energies on competition and guarding, rather than caregiving. In several computer simulations under a wide range of conditions, allocation to caregiving is very low, even when the potential effect of care is large. This is partially explained because the payoffs from mating competition are frequency dependent (as care is not) and pay so well it's not evolutionarily stable for competition to remain rare. Additionally, males face a "Social dilemma: shifting efforts to care rather than mate acquisition/guarding should give an advantage to free-riding competitors" (Gavrilets 2012). Males must allocate resources to production, but if no resources go toward preventing theft (by competing for and guarding mates), anyone can lose paternity to theft. So, males also dedicate resources to mate guarding to prevent theft by cuckoldry.

Hawkes et al. (1995) models this dilemma in terms of evolutionary game theory and finds the equilibrium strategy shifts in favor of conflict and equal incomes for competitors. As the number of contestants increases or as individual production increases, there are more opportunities to steal or there is more paternity to steal, and participants allocate greater resources toward mate guarding

(competition). The stable strategy again allocates few resources to caregiving.

The computer simulations used all assume a population of 100, with each group containing five males. Populations are modeled when males are less efficient at child care than females and when males are as efficient at care as females. With both parameters, males devote their time to mate guarding rather than offspring care. Hawkes then attempts to reconcile the models with observations of male care. In the past male care was explained by an increase in survival of young, or as an effect of pair-bonding. However even when mates are pair-bonded, more recent research has suggested male care is not essential for the success of offspring. Strong mating competition, rather than payoffs for care, enforces monogamy (Davies 1992).

Conclusion

Under a variety of conditions, it appears to be more evolutionarily stable for males to devote their resources toward mate guarding or mate acquisition. Evolutionary stable strategies for males generally reinforce devoting little care for their offspring, because of low pay-off rates.

Five-Factor Model

Guy Madison
Umeå University, Umeå, Sweden

Synonyms

Agreeableness; Conscientiousness; Extraversion;
Neuroticism; Openness to experience; Personality
dimensions; Personality traits; The Big Five

Definition

A model of the overarching dimensions of behavioral, cognitive, and emotional tendencies that account for a large proportion of the variability in these regards across individuals in a population.

Introduction

People differ in their characteristic patterns of thinking, emotions, and behavioral tendencies, which is known as personality. Each individual is typically rather stable in these patterns across

different situations and across the course of life, which means that a person's previous patterns are predictive for their future patterns. To utilize such information on the group level, (1) it must be reduced to a manageable number of dimensions, (2) these dimensions have to account for a substantial proportion of the variability across individuals, and (3) they have to be reliably measured. This is what personality models attempt to do. The first point can be approached top-down, through deductive reasoning based on theoretical assumptions, biological, social, evolutionary, or neurological knowledge, or some combination thereof. Once this is done, instruments can be devised to measure the proposed dimensions, which will show how much of the variability can be accounted for. Instead, the five-factor model (FFM), or its closely related Big Five model, applies a bottom-up approach to determine the dimensions, based on the covariance structure of an exhaustive set of personality indicators. These indicators could be peer ratings or observations of behaviors, but are almost exclusively self-ratings of initially thousands of words that could describe personality traits. Factor analysis is then used to indicate how many dimensions are optimal for explaining as much as possible of the variance while still rendering each dimension interpretable in terms of a consistent meaning of the words that aggregate in each factor. Seminal work along these lines was done by Gordon Allport in the 1930s (John and Robins 1993), J. P. Guilford in the 1940s and 1950s, and Raymond Cattell, who developed the influential 16PF model (Cattell et al. 1988).

The Big Five Factors and Specific Traits for the Most Common Models

The Big Five are often referred to as their acronym OCEAN:

Openness to experience. Those who score high on this are creative, imaginative, aesthetic, artistic, and open to new ideas, in contrast to those who are practical, conventional, and fixed in their ways.

Conscientiousness. Those high in C tend to be organized, directed, hardworking, persistent, and controlling, in contrast to being spontaneous, careless, sloppy, and prone to addiction.

Extraversion. The extraverted are outgoing, enthusiastic, and active, seek novelty and excitement, and experience positive emotions strongly, while those who score low on E are aloof, quiet, independent, cautious, introverted, and enjoy being alone.

Agreeableness. Trusting, cooperative, altruistic, and slow to anger, as opposed to being stingy, uncooperative, and hostile.

Neuroticism. Prone to stress, worry, and negative emotions and who require order. The opposite is emotionally stable and tolerable to risks and uncertainty.

Thus, each factor is conceived of as a spectrum along which every individual can be positioned, and that is named after one extreme on that spectrum. Most of the personality models that have been proposed within academic psychology have eventually been abandoned and forgotten, and many have effectively been subsumed by the FFM. The main exceptions include Cattell's 16PF, the HEXACO model, and John Holland's RIASEC model of interests for vocational choice. Cattell's 16 factors are Warmth, Reasoning, Emotional stability, Dominance, Liveliness, Rule-consciousness, Social boldness, Sensitivity, Vigilance, Abstractedness, Privateness, Apprehension, Openness to change, Self-reliance, Perfectionism, and Tension. The two latter have six factors each. RIASEC stands for Realistic, Investigative, Artistic, Social, Enterprising, and Conventional (Holland 1997). Although these are apparently quite different from the Big Five, there is a large overlap (McKay and Tokar 2012). The HEXACO model adds a factor called Honesty-Humility and replaces Neuroticism with Emotionality, but the interpretations of the remaining factors also differ somewhat from the FFM (Lee and Ashton 2012).

There are several well-known and often used instruments to measure the Big Five. One of the most comprehensive is the NEO-PI-R, which has 240 items, 8 for each of the 30 facets, which are

then aggregated 6 and 6 to obtain the 5 factors according to the following structure: Openness to experience (O1 Fantasy, O2 Aesthetics, O3 Feelings, O4 Actions, O5 Ideas, O6 Values); Conscientiousness (C1 Competence, C2 Order, C3 Dutifulness, C4 Achievement Striving, C5 Self-Discipline, C6 Deliberation); Extraversion (E1 Warmth, E2 Gregariousness, E3 Assertiveness, E4 Activity, E5 Excitement Seeking, E6 Positive Emotion); Agreeableness (A1 Trust, A2 Straightforwardness, A3 Altruism, A4 Compliance, A5 Modesty, A6 Tendermindedness); and Neuroticism (N1 Anxiety, N2 Hostility, N3 Depression, N4 Self-Consciousness, N5 Impulsiveness, N6 Vulnerability to Stress) (Costa and McCrae 2008).

The NEO-PI-R is proprietary, but there is a family of open-access instruments called International Personality Item Pool (IPIP), with 300-, 120-, and 60-item versions. It takes around 20–30 minutes to fill out the 240 NEO-PI-R items, but if one is not specifically interested in the facets, there are abridged versions that only yield the five factors, the most common being the Big Five Inventory (BFI-44) with 44 items (John et al. 1991) and the Ten-Item Personality Inventory (TIPI) with 10 items (Rammstedt and John 2007).

Which Model Is Best?

For the purpose of most research that considers personality traits, we may not have to choose between bottom-up and top-down or even among specific models. Although they might have different numbers of traits with different names, they tend to share some level of aggregation at which they essentially account for the same main dimensions. For example, the most fine-grained level has 10 traits in Guilford's model, 16 in Cattell's 16PF, and 30 in Costa and McCrae's NEO-PI-R instrument (Costa and McCrae 1992, 2008). However, all these traits can be aggregated so that they largely conform to the five-factor model (For comparisons of many personality models, see, e.g., <http://wbphillipskhs.pbworks.com/w/file/fetch/106978269/big-five-personality.pdf>

and <http://www.psychologycharts.com/big-five-personality-traits.html>.). At this level of aggregation, twin studies therefore indicate a heritability of traits in the region of 50% regardless of model (Nettle 2007; Bouchard and McGue 2018). Any model can be further aggregated into super-factors like Alpha and Beta (Digman 1997), Stability and Plasticity (DeYoung et al. 2002), the Giant Three (P-E-N, see Eysenck et al. 1992), and the General Factor of Personality (van der Linden et al. 2010) (GFP). If the research question considers more narrow or specific traits than the Big Five, one needs to choose the model that encompasses those. For example, a ten-factor solution that is intermediate to the Big Five and the 30 NEO facets seems to be quite useful (DeYoung et al. 2007).

Conclusion

The five-factor model has become widely accepted and is currently the most commonly used in behavioral research. It measures individual differences in personality traits with documented validity. Group differences is of particular interest and importance within evolutionary psychology, and reliable national-level differences have been reported (McCrae 2002; McCrae et al. 2005; Allik et al. 2017). However, national differences should be interpreted with caution, as their validity may be compromised by the self-report method. If a group is very high in conscientiousness, for example, a member of that group will rate herself in relation to her peers and thus underestimate her conscientiousness. Consequently, the group mean will be similar to, or even below that of, groups with lower conscientiousness (Heine et al. 2008). To what extent this applies to groups within the same society remains an open question. For example, sex differences tend to be large (Verweij et al. 2016; Del Giudice et al. 2012) and consistent across nations (Feingold 1994; Lipka 2010).

Although there are many competing conceptualizations of personality, which have more or less, and to some extent different traits, the five-factor model encompasses most of these. Its popularity

probably stems from its ability to integrate most conceptions of personality and stimulate research, and the availability of public domain instruments with documented psychometric properties. For many research applications, it is simply “good enough.”

Fixed Action Patterns

Veronica Kraft

Department of Psychology, University of Arizona, Tucson, AZ, USA

Synonyms

[Fixed behavior patterns](#); [Modal action patterns](#)

Definition

Inherent behaviors that occur invariantly in succession and almost always execute to completion regardless of any changes in the initial sign stimulus.

Introduction

Behaviors are unique to each species. Every species has a common goal – to be fit and live long enough to reproduce; to replicate their genes. Each generation of a species has the potential to adapt to the ever-changing environment and increase their fitness, which is often done in utilizing the most efficient behaviors. Fixed action patterns (FAP), or fixed behavior patterns, are an innate sequence of behaviors that have been “hard-wired” into an individual through the evolutionary history of its species. These patterns tend to be triggered by specific stimuli and almost always run to completion – the cascade of behaviors happen without the organism even consciously reacting, they simply just occur and fully execute to completion due to a natural response (Baum 2017).

Fixed action patterns in nesting gray geese

The idea that fixed behaviors occur due to a specific stimulus came about at the beginning of the twentieth century during the start of the field of ethology. A fixed action pattern is not learned and cannot be altered. This specialized sequence of behaviors toward stimuli must be shown to be acted out by the entire species and may be accidentally initiated by a different stimulus. Lorenz and Tinbergen demonstrated this phenomenon with a graylag goose while nesting. The female goose would reach beyond an egg that rolled out of the nest, always using the underside of her bill to roll the egg back toward the nest. In experimental conditions, even if the real egg is replaced with a plastic egg, the female goose will continue to roll the egg back to the nest in the same fashion (Goodenough et al. 2010). This emphasized Lorenz's points concerning fixed action patterns – they are innate, unlearned behaviors that the entire population exhibits and they may sometimes be utilized in inappropriate situations but will ultimately always run to completion. There were some that had their doubts about the entirely “fixed” nature of these behaviors, which will be discussed below with modal action patterns.

Variance Versus Invariance: Arguments Against FAP/MAP

A. Mather 1986

One of the main arguments with FAP was with the overall rigidity of the concept – there was no room for any type of variance with Lorenz's original explanation. The behaviors being examined were entirely too formal with hardly any room for discrepancies, which many ethologists felt simply was not true. There were some in the field that believed that these “fixed” patterns of behavior could show variance when influenced by cognitive or environmental factors (Gadbois et al. 2015). The sequence of behaviors may be genetically ingrained in the species to be performed in certain ways, but only when given a specific, innately recognized stimulus. Other cognitive

functions or changes to the common environment could cause behavior to vary slightly, showing adjustment to the current situation. This is where modal action patterns came into theory – modal allowed statistical variability within the observed patterns, arguing that not all patterns were concrete and indefinitely similar in every circumstance as “fixed” previously described. George Barlow also theorized that the only “fixed” part of these sequences of behavior was their statistical inference, otherwise these behaviors could be very flexible (Pellis et al. 2009). The common argument usually does fall among both theories – stating that technically both are true to some extent. While these behaviors are basically entirely innate and do follow through as a “pattern” that is stereotypical to that species, many also consider that there are influences from the current environment. Mather (1986) examined sand digging techniques compared across seven different *Sepia officinalis*, a cephalopodic mollusk, when conditioned were changed. A. Mather found that by changing the sand grain size, the behaviors that were once common across all seven mollusks (blow forward, blow backward, wiggle) now varied based on the size of the grains of sand. This showed that while basic behavior may be genetically hardwired, it can also be influenced by (in this case) peripheral feedback.

Conclusion

Fixed action patterns were first theorized to be programmed sequences of behavior that could be found in every member of a species – consistent behaviors that acted the same toward a given sign stimulus that would run to completion regardless of any other factors. Beginning ethologists believed that certain sequences of behavior could be operational; these patterns would be seen throughout the entire species, regardless of any other influence on the individual from internal factors or the environment, with absolutely no evidence of variance. Later ethologists theorized that this could not be the case, and began to explore the idea of modal action patterns – the

possibility that there may be evidence of variance among these common behavioral patterns within the same species. The debate is still open today, but many believe that like with most things in this world, nothing is perfect, not even a genetically programmed behavior pattern. This would mean that these sequences of behavior are open to individual interpretation, regardless of the innate behaviors of the entire species, and they may be influenced by external environmental factors.

Fluctuating Asymmetry

Stefan Van Dongen
Antwerp University, Antwerp, Belgium

Synonyms

Directionally random morphological asymmetries; Left-right differences

Definition

Developmental instability (DI) is the inability of an organism to buffer its development adequately against random perturbations – has been put forward as a biological signal of (genetic) quality. As increased DI increases morphological asymmetries (fluctuating asymmetry), it has been predicted that women should have a preference for more symmetric phenotypes. While several studies point in this direction, the adaptive value of this preference is not fully understood. This chapter highlights the current state of knowledge and important caveats that require further study.

Introduction

Asymmetry as a measure of stress and quality: The adaptive value of mate preferences for specific traits requires that these features signal “individual quality” in terms of direct or indirect benefits. A specific trait of interest in evolutionary biology and behavioral ecology which potentially signals “quality” is morphological symmetry. In bilaterally symmetric organisms, perfect symmetry is often the norm, in the sense that on the average, the differences between the trait values (e.g., length of a bone) on left and right equals zero. However, most individuals in such populations are not perfectly symmetric. This variation in asymmetry is assumed to result from the accumulation of developmental perturbation, i.e., small mistakes that occur during growth/development. Consequently, individuals which are less able to correct for these developmental mistakes, a process termed developmental instability (DI), will develop a less symmetric phenotype. As the direction in which the asymmetry develops is not relevant, this type of asymmetry is termed fluctuating asymmetry (FA) (Fig. 1). When at the population level, the average asymmetry deviates from zero, directional asymmetry (DA) is

Fluctuating Asymmetry, Fig. 1 Distribution of three types of asymmetry. In the case of fluctuating asymmetry, all variation between *left* and *right* are assumed to reflect the accumulation of developmental perturbations. Higher asymmetries, i.e., in the tails of the distribution indicated in

more *orange-red* color, correspond to higher developmental instability. In the case of directional asymmetry and antisymmetry, the average population asymmetry is assumed not to be related to developmental instability, but variation around it does

observed. As a third type of asymmetry, anti-symmetry is distinguished, where the distribution of asymmetry follows a bimodal pattern (Palmer and Strobeck 1986) (Fig. 1).

The term fluctuating asymmetry was first coined by Ludwig in 1932 (Palmer and Strobeck 1986). After some time, FA research started to bloom during the mid of the twentieth century, focusing on associations between FA and different types of stress (pollution, pesticides, genetic variation). Until the early 1990s, studies mainly focused on population level FA, after which we witnessed a shift towards the use of FA as a measure of individual (genetic) quality, mostly through observations of FA-fitness associations and the study of the genetic basis of FA and DI. In spite of being a very appealing paradigm – where complex biological features like fitness and individual (genetic) quality could be measured easily by measuring traits on the left and right hand side of an organism – it became clear that observed patterns were often not highly repeatable or consistent, leading to quite intensive debates in the scientific literature. Nevertheless, this variation of patterns among studies deserves further research in order to understand the biological causes of heterogeneity among studies (e.g., Van Dongen and Gangestad 2011). At present, one can safely conclude that at least in some cases, FA increases with decreasing individual “quality” and increases with levels of stress experienced during development. In addition, it seems fair to conclude that FA cannot be considered as a consistent signal of stress and quality, but this is probably true for any other measure.

Fluctuating asymmetry in humans: The study of fluctuating asymmetry in humans already started about 40 years ago. To my knowledge, one of the first studies to report associations between FA and developmental perturbations is the work by Woolf and Gianas in 1976 (see Van Dongen and Gangestad 2011 for reference), showing an association between congenital cleft lip and FA. Over several decades, a large amount of human FA literature has accumulated. Patterns correspond to those in other taxonomic groups, in the sense that overall there was a robust and highly statistically significant association between

FA and the various “quality” measures, but additionally, the strength of association varied substantially among studies (Van Dongen and Gangestad 2011). The reasons for this heterogeneity remain largely unknown. In addition, there were indications that the literature showed publication bias where null results are less likely to be published. While there is little reason to doubt that morphological asymmetries do signal health or quality in some cases, the generality of these associations is highly questionable. Indeed, a large recent study found no association between health and facial FA (Pound et al. 2014). In human fetuses, developmental perturbations need to be very far-reaching (often-lethal birth defects that emerge during early organogenesis and extreme genetic abnormalities) in order to increase limb FA (Bots et al. 2014). Clearly, it remains very difficult to predict if and when FA increases with decreasing health or quality. Therefore, the adaptive value of preferences for symmetry remains speculative.

Asymmetry and male attractiveness: Along with studies investigating associations between FA and attractiveness in many species, research into these patterns were also initiated in humans in the early 1990s. Experiments follow two approaches, either by manipulating symmetry of pictures generating stimuli for evaluation by opposite sex raters or by studying the association between natural asymmetry levels by presenting natural pictures for evaluation of attractiveness. Both approaches have their pros and cons. Manipulating symmetry has the advantage that pictures can be presented in combination with the natural versions to identify the most attractive one. This is a statistically powerful approach, indeed leading to stronger effects, but can also lead to counterintuitive results where symmetrized faces were judged to be less attractive. A potential drawback of manipulating asymmetry in pictures is the possible breakup of associations between asymmetry and other candidate markers of attractiveness and quality, and potentially leading to an unnatural presentation of morphological asymmetries. In addition, the signal of such studies is likely to be related to the degree of manipulation of levels of FA (Van Dongen 2011). Studies investigating

associations between FA in natural pictures and their attractiveness from opposite sex raters do not suffer from these disadvantages, but likely require relative high sample sizes because many other aspects of attractiveness may blur associations with FA. In a review of this literature Van Dongen (2011) pointed out that: (i) overall sample sizes of studies of associations between FA and attractiveness were relatively small; (ii) the literature showed signatures of publication bias; (iii) there is likely to be a direct role of the observable asymmetry in determining physical attractiveness, weakening the importance of developmental instability and thus compromising the adaptive basis of preferences for symmetry; and (iv) there was stronger evidence for an association between FA and other forms of attractiveness, like scent, dance, and voice. The latter was, however, based on relatively few studies. More recently, it has been emphasized that the overall weak – if any – associations between FA and physical attractiveness may be due to the fact that FA is often summarized as a combination of FA in several linear measurements, while multivariate shape analyses may be more powerful. However, recent studies did not find associations between facial attractiveness and 2D or 3D shaped FA (e.g., Farrera et al. 2015).

Overall, women's preferences for physical symmetry seem to be supported mainly when symmetry of pictures are manipulated, yet less convincingly so when evaluating natural levels of asymmetry. It is important to note though that women's choosiness depends on several factors, including own perceived attractiveness, use of hormonal anticonceptions, timing in menstrual cycle, context of choice (long- vs. short-term relationship), and the presence of signals of disease prevalence (Windhager et al. 2011). The most common explanation is that women's preference for particular traits, including FA, is adaptive in a good genes context, where potential fathers are selected to provide genetic characteristics like high immunity. This is why some have argued that both sexual dimorphism and FA are both signals of good genes, but a review of this literature did not find strong support for this claim (Van Dongen and Gangestad 2011). This is also in line

with the recent very large study concluding that women's preferences for symmetry – if adaptive – most likely evolved “to motivate avoidance of markers of substantial developmental disturbance and significant pathology” (Pound et al. 2014). This conclusion is also supported by studies in human fetuses where FA is only increased when development is severely disrupted (Bots et al. 2014). Nevertheless, it is also important to note that most of the FA research in humans has been conducted in a relatively wealthy and well-nourished environment in which effects of ill health on development are perhaps likely to be minimal (Van Dongen 2011; Pound et al. 2014).

Conclusion

When the concept of FA gained widespread notice in human evolutionary biology, expectations were high, probably unrealistically high (Van Dongen and Gangestad 2011). Over the last two decades, these expectations were toned down. At the same time, by no means does DI offer a simple, complete explanation of maladaptation, good genes, attractiveness, and so on. Despite the considerable amount of work that has been done to date, a variety of important questions remain unanswered, and more work is needed to provide a full understanding. In general, important caveats have been reported elsewhere, and priority should be given to the link between FA and different aspects of health and quality. Research in sub-optimal non-Western societies may be most relevant here (Van Dongen 2011; Van Dongen and Gangestad 2011; Pound et al. 2014). More specifically in the context of women's preferences for symmetry three important aspects remain crucial. Firstly, there is a need to increase our understanding as to why there is such a discrepancy in strength of effects between studies in which pictures are manipulated and those studying natural variation in FA. Second, many traits, including human face and body, show DA. While this source of variation is often ignored, this may not be correct because: (i) preferences for faces may be related to traits not showing DA only (Simmons et al. 2004), (ii) stress may also

increase DA (Klingenberg et al. 2013), and (iii) DA also affects attractiveness ratings (Meyer-Marcotti et al. 2011). Finally, (facial) FA is often expressed as a composite average across different traits. However, asymmetries of different areas in the face differ in their impact on visual attractiveness, calling for a thorough 3D shape analysis (Meyer-Marcotti et al. 2011). Clearly, with the growing possibilities of high-density surface scans of faces and bodies very powerful and detailed analyses are now easily accessible and can be expected to increase our understanding of the adaptive relevance of asymmetries in determining opposite sex attractiveness.

Synonyms

[Fluid carrying tools](#)

Definition

Locomoting while transporting a tool that holds or has a fluid into or on top.

Introduction

There are three types of tools used by primates to obtain fluids: containers, absorbents (or sponges), and probes (dipping tools). Primates have been observed to use all three types of tools both in the wild and in captivity. However, while there are reports of primates in captivity using tools to transport fluids, this has not been reported for primates in the wild.

Evidence from the Wild

Wild primates use and make tools to obtain water, honey, sap, and other fluids (reviewed in Shumaker et al. 2011; Wynn et al. 2011).

Chimpanzees use (1) folded leaves as simple containers to drink water; (2) leaves, plant fibers, stems, fruits, and moss as sponges to absorb water, plant fluids, and occasionally fluids from inside a prey's skull or a fruit shell and even palm wine from containers left by humans in forest trees; and (3) twigs, branches, vines, and sticks as probes to dip for honey or water. *Bonobos* use moss as sponges to drink water. *Orangutans* use (1) leaves as containers to scoop water from ground puddles, (2) crumpled leaves as sponges to drink water, and (3) branches as probes to extract honey and leafy branches to dip for water from tree holes. *Capuchins* use (1) leaves as containers to drink water from tree cavities, (2) sticks, vines, and branches as probes to access honey and water, and (3) once they used a crumpled leaf as a sponge to absorb water from a tree hole.

However, no transport of fluids using tools has been reported for wild primates.

Evidence from Captivity

Captive primates have been observed to use and make tools to obtain water and other fluids (reviewed in Shumaker et al. 2011) and to transport such fluids using these tools.

Great Apes

Chimpanzees, *bonobos*, *orangutans*, and *gorillas* use a wide variety of materials as containers,

sponges, and probes to obtain fluids spontaneously, during experiments, or from artificial feeders (e.g. termite mounds). They use natural materials from plants (leaves, sticks, twigs, branches, fruit shells, bark, straw, grass, fibers) or animals (eggshells) and human-made materials (tableware, textiles, paper, toys, cans, bottles, hats, buckets) to get a variety of fluids such as water, juice, honey, syrup, or yogurt.

There are reports of all great ape species carrying fluids using tools. For example, *chimpanzees* used an empty coconut shell to collect water and transported it to a different place to drink (McGrew 1992) and plastic bottles to obtain water from a moat also carrying them elsewhere to drink (see Fig. 1). A *bonobo* filled a plastic bottle with water from a lake and carried it to a fence in her enclosure where she seemed to be pretending to drink from it (Gruber et al. 2010). *Orangutans* contained fluids in vessels and carried them within their enclosures (Shumaker et al. 2011). *Gorillas* used buckets to collect water and transported them around their exhibit (Margulis et al. 2012).

Rehabilitant and pet great apes, or those who have been part of language experiments, easily utilize human-made containers and use them to carry fluids.

White-handed gibbons were observed to use pieces of cloth as sponges to absorb water and a leaf as a container and later as a sponge to obtain water from a pool, but they were not reported to transport these fluid-containing tools.

Monkeys

Capuchin monkeys spontaneously and during experiments use tools provided by humans or made from natural materials as containers, sponges, and probes to get water and fluid foods. They have also been observed carrying these tools. For example, scoops containing water and sponges soaked with juice were both transported to different parts of their cage (Westergaard and Frigaszy 1987).

Yellow baboons used twigs and leaves as probes to extract sweet syrup from a container with a narrow opening in one experiment and paper towels to absorb juice from a container in a second experiment; they transported the soaked paper towels to consume the juice away from the

Fluid Transportation, Fig. 1 A chimpanzee at the Kristiansand Zoo in Norway fills up an empty plastic bottle with water from a moat (a) and transports it several meters (b) before drinking. Courtesy of Tanya C. Minchin

container (Westergaard 1992). *Rhesus monkeys* used different human-made objects to scoop and transport drinking water (Parks and Novak 1993). *Squirrel monkeys* spontaneously used cups to contain water and often transported them to the back part of their cage for consumption (Buckmaster et al. 2015).

There are reports of other monkey species in captivity using tools to obtain fluids during experiments or spontaneously. A chacma baboon used a blade of grass as a probe to extract the oils from a pipe to eat them. Lion-tailed macaques used sticks to extract fluid food from holes and tubes. Finally, a *Sulawesi macaque* used sticks and branches to dip for fluid food from a tube. However, no transport of fluids with tools was reported for these species.

Conclusion

Wild chimpanzees, orangutans, and capuchin monkeys use three tool types (container, sponge, and probe) and bonobos one type (sponge) to acquire

fluids. However, despite the extensive evidence of such tool use, there are no reported observations of wild primates using tools to carry fluids.

There are numerous reports of captive chimpanzees, orangutans, gorillas, bonobos, and capuchin monkeys employing a variety of objects as tools to obtain fluids, but only a few studies have described the transport of fluids using these tools. It cannot be discarded, however, that some instances of tool transportation after having obtained and while still holding the fluid have simply not been reported in captivity.

Why wild primates lack tools to transport fluids? In captivity, a benefit of using tools for transporting a fluid seems to be to avoid competition with conspecifics for access to that fluid (Westergaard and Frigaszy 1987; Westergaard 1992; Buckmaster et al. 2015). Thus, the use of tools to carry fluids could offer an advantage to wild primates during competition for fluid resources (e.g., honey). However, in contrast to most tools used by captive primates to transport fluids, the tools utilized by wild primates hold

only minimal amounts of fluid and are not efficient for transport. Plant raw materials to make efficient, long-distance containers are available to wild primates, but without bipedal locomotion or a home base containers cannot be carried efficiently or stored and thus may not be necessary tools for primates in the wild (McGrew 2004).

Definitions

fMRI is an advanced magnetic resonance imaging application for functional brain imaging.

Introduction

Functional magnetic resonance imaging (fMRI) uses the different magnetic properties of oxygenated and deoxygenated hemoglobin to look for blood flow patterns in different areas of the brain in relation to different sensory stimuli and motor activities. The subjects are presented with visual, auditory, and sensory stimuli or asked to perform some simple motor tasks while within the MRI scanner. fMRI can reveal brain areas activated with these processes. Due to absence of radiation, high spatial resolution, and moderately high

temporal resolution, fMRI is replacing PET for functional brain imaging.

Principles of fMRI

fMRI is based on the concept of Blood Oxygen Level Dependent (BOLD) imaging. BOLD fMRI uses the different magnetic properties of oxygenated and deoxygenated hemoglobin to identify regional blood flow changes in brain, in response to a specific task. Oxygenated hemoglobin (oxyhemoglobin) is a diamagnetic substance which means it is repelled by externally applied magnetic field. In contrast, deoxygenated hemoglobin (deoxyhemoglobin) is a paramagnetic substance which means it is weakly attracted by an externally applied magnetic field. So during an MRI scan when external magnetic field is applied, deoxyhemoglobin increases local field inhomogeneity (Kornienko and Pronin 2009).

When a patient is asked to perform a particular activity (e.g., speaking, singing, finger thumb apposition), this results in increased neuronal activity. So there is increased blood flow to the activated area to meet the increased oxygen requirement which is much more above the resting state of brain. Increased oxygen delivery results in increased concentration of oxyhemoglobin with corresponding decrease in deoxyhemoglobin. Any area of signal change that correlates with neurological task is identified and compared with corresponding high resolution anatomical image. So what we measure in fMRI is not the neuronal activity but the local hemodynamic response to such activity. It may be noted that PET scan which is another modality of functional brain imaging, measures neuronal glucose metabolism (Adam et al. 2014).

Advantages of fMRI

- High spatial resolution (1–4 mm thin sections) provide excellent anatomical image.
- Moderately high temporal resolution (0.1–1 s).
- No use of radiocontrast isotope. So there is no health hazard and it is absolutely safe.

- It is a noninvasive procedure.
- Both functional and anatomical images can be obtained in one session.
- It is cost effective and doesn't cost much extra than a conventional MRI.

Limitations of fMRI

- It can't be quantified. It is a qualitative measure of brain function.
This technique is very sensitive to movements. So, all tests should be done without head movement. For example, speaking and hand apposition.
- Artifacts are more common in areas adjacent to air (sinuses). So interpreting brain areas close to paranasal sinus (orbitofrontal cortex and medial temporal cortex; the emotional brain areas) is difficult.

fMRI Examination: Task Protocol

In fMRI, patient or a subject is given a task and the region of brain activated are assessed. The following types of tasks are often employed.

1. Motor: For example, finger tapping, apposition of thumb with index finger, it localizes the hand representation in primary motor cortex (Brodmann's area 4).
2. Language and cognitive: visual and auditory commands for language examination.
3. Passive paradigm: tactile, auditory, visual stimuli. For example, light flashing activates visual area (Brodmann's area 17,18,19) in occipital cortex. Auditory area (Brodmann's area 41,42) in posterior part of superior temporal gyrus can be activated by sound tones.

Clinical Applications of fMRI

(Atlas 2016; Logothetis 2008; Detre and Floyd 2001)

1. *Understanding functional brain areas:* As previously described, fMRI helps in localizing

functional brain areas by performing specific tasks for that area.

2. *Understanding psychiatric diseases:* fMRI has been used since its first uses to study neuronal basis of mental illness. The major psychiatric disorders like schizophrenia and depression were previously considered because of disordered neurological circuitry widely distributed throughout the brain. But recent fMRI studies have shown that there are certain areas of brain that shows altered activation pattern in certain psychiatric diseases. For example, major depression is associated with hyperactivity in anterior cingulate gyrus. And effective pharmacological treatment for depression results in normalization of this activity. Similarly schizophrenia is associated with decreased activity in anterior cingulate gyrus
3. *Dementia:* fMRI at present is not performed routinely in evaluation of patients of dementia, but it offers promise in future for earliest detection of prodromal dementia. fMRI studies till date shows altered activation pattern in memory specific brain regions like medial temporal lobe, hippocampus in patients of early stage dementia
4. *Determination of hemispheric dominance for language:* In general population about 95% are right handed. Left hemisphere is dominant in about 99% of right handers, in about 60% of lefties. Among the rest 40% of left handers, 20% have right hemispheric dominance and rest 20% have mixed dominance. (Campbell Jr and DeJong 2013). Determination of hemispheric dominance is very much important, particularly in presurgical evaluation and planning of patients to be considered for epilepsy surgery or surgery for any intracranial tumor.
5. *Neurosurgical planning:* fMRI delineates the functional areas of brain preoperatively, so helping the neurosurgeon predicting the surgical approach and postsurgical disability. One of major application of fMRI is in epilepsy and most importantly temporal lobe epilepsy syndromes. Here task correlated localization of language and memory areas and localization of ictal and paroxysmal phenomena helps in

predicting postsurgical risk and success of surgery. fMRI is also a useful tool in patients of primary brain tumor. Presurgically, these patients are imaged for anatomical margin of tumor and nearby functional areas. A distance of 1 cm or more between the functional cortex as localized by fMRI and tumor margin is found to be associated with significantly less risk of postoperative loss of function.

Conclusion

Due to absence of radiation, high spatial resolution, and moderately high temporal resolution, fMRI is replacing PET for functional brain imaging. fMRI finds utility in management of brain diseases and in neuroscience research. Major clinical applications of fMRI include surgical planning of patients planned for epilepsy surgery and brain tumor surgery. Its role in neurological and psychological disorders has been well recognized and new applications are emerging day by day.

Food Aversions and Cravings

Caitlyn D. Placek
 Ball State University, Muncie, IN, USA

Synonyms

[Dietary preferences](#); [Dietary shifts](#)

Introduction

The sudden shift in dietary preferences, such as the onset of food aversions and unusual cravings, is considered a hallmark of pregnancy. Aversions and cravings can be understood as strong urges to avoid or consume certain foods and nonfood substances regardless of the cultural norms or other

perceived health indicators that aim to regulate avoidance or consumption. Several influential evolutionary theories have been put forth to explain these shifts, and accumulating evidence suggests that environmental, biological, and cultural factors all play a role in shaping women's dietary preferences.

Dietary Aversions

Dietary aversions in pregnancy are characterized by distaste or disgust toward a specific food item, typically beginning during the first trimester, and coincide with nausea and vomiting ("morning sickness"; Flaxman and Sherman 2000). The leading hypotheses to explain dietary aversions include *maternal-fetal protection* and *resource scarcity*.

From an evolutionary perspective, the longest-standing hypothesis, the *maternal-fetal protection hypothesis*, states that food aversions protect mothers from ingesting substances that could pose a threat to themselves and the developing fetus and focuses on immunological changes women experience during pregnancy (Hook 1976; Fessler 2002; Flaxman and Sherman 2000; Profet 1988). In the first trimester, the maternal adaptive immune system shifts to support growth and development of the placenta and fetus. As a result, both mothers and fetuses are particularly vulnerable to the harmful effects of certain pathogens (e.g., malaria and listeria) and toxins (e.g., nicotine). Hook (1976) and Profet (1988) initially emphasized that certain plant teratogens, which cause birth defects or miscarriage, should lead women to experience aversions to bitter-tasting, pungent, plant-based items. A cross-cultural test of this hypothesis found, however, that although dietary shifts and morning sickness co-occurred in the first trimester, women's food aversions targeted meat products and not plant-based items (Flaxman and Sherman 2000). Fessler (2002) therefore concluded that feeling averse to meat is adaptive since animal products are particularly susceptible to pathogens that can pose a threat to pregnancy.

Although the maternal-fetal protection hypothesis has generated several lines of evidence, food aversions do not always target items that are considered evolutionarily harmful; instead, in some cases, women report aversions to innocuous staple foods (Demissie et al. 1998; Placek et al. 2017). In these studies, researchers highlight the role of resource scarcity and cultural factors in shaping the timing and expression of pregnancy food aversions. In Southern Ethiopia, for example, women were averse to staple cereals and reported cravings for meat and other animal products since these items were scarce (Demissie et al. 1998).

Dietary Cravings

Dietary cravings in pregnancy can be defined as the compulsive desire and ingestion of food or nonfood substances. Pregnant women are known for craving calorically and nutrient-dense foods, such as sweets and fruits, along with odd combinations such as “pickles and ice cream,” or pica substances, such as clay and chalk (Flaxman and Sherman 2000; Placek and Hagen 2013; Young 2010). Several hypotheses have been proposed for pregnancy cravings: *maternal-fetal protection*, *nutrient-seeking*, *resource scarcity*, and *social bargaining*.

Similar to aversions, one evolutionary explanation for dietary cravings is that they provide defense against toxins and pathogens during the first trimester when women are particularly vulnerable (the *maternal-fetal protection hypothesis*; Fessler 2002). Women’s vulnerability is further intensified by metabolic shifts associated with placental development, which impact bioavailability of dietary antioxidants (King 2000). Accordingly, women should report cravings for substances rich in defensive compounds, such as antioxidants. In support of this hypothesis, cross-cultural studies of food cravings have shown that women typically report cravings for fruit, fruit juices, and unripe fruits (Flaxman and Sherman 2000; Placek 2017). Cravings and subsequent consumption of unripe fruits, which are high in vitamin C, can reduce teratogenic effects of

environmental toxins (Fessler 2002). Furthermore, unripe fruits tend to contain tannins, which can aid in the treatment of ulcerated or inflamed tissues and also provide a stable source of antioxidants. The craving for culturally defined nonfood items, “pica,” is also common during pregnancy (Young 2010). Support for the maternal-fetal protection hypothesis of pica stems from the evidence that certain pica substances have the capacity to detoxify specific ingested chemicals, such as tannins (Young 2010), and consumption is often linked to external cues of pathogen exposure (Placek and Hagen 2013).

The *nutrient-seeking hypothesis* of cravings proposes that cravings target foods dense in calories and nutrients after the tenth week of pregnancy when women need to store excess fat to support fetal growth and development (King 2000). Evidence for this hypothesis is illustrated in a study conducted in Tanzania which found that pregnant women in the second trimester craved a diversity of nutrient-rich foods (Nyaruhucha, 2009). Accumulating evidence for pica cravings paints a similar picture: women often consume nonfood substances during periods when they are deficient in certain micronutrients, such as iron, zinc, and calcium, suggesting that they might not be meeting nutritional demands from regular food sources (Young 2010). The nutrient-seeking hypothesis is similar to the *resource scarcity* hypothesis, but not mutually exclusive. The *resource scarcity* hypothesis proposes that cravings for certain foods and nonfoods are heightened in resource-scarce environments. This perspective differs from the nutrient-seeking hypothesis in that women might experience cravings for substances that provide no nutritional benefits. Pregnant women in South Ethiopia, for example, craved meat and vegetables, two items implicated in the maternal-fetal protection hypothesis that were otherwise unavailable due to a lack of resources (Demissie et al. 1998). Furthermore, pica substances, such as soil, have been used to quell hunger at different points of time, and consumption has been associated with physical indicators of resource scarcity (Placek and Hagen 2013; Young 2010). The resource scarcity hypothesis, however, is not typically

accepted as the overarching explanation for consumption of pica substances, primarily due to observations that substances are frequently craved between meals and consumed in such small quantities that consumers would be unlikely to feel satiated (Young 2010).

The *social bargaining* hypothesis for cravings in pregnancy proposes that women who perceive an uncertain future for their offspring crave items that are either locally viewed as dangerous or dangerous in light of evolutionary theory (e.g., toxic plant compounds or pathogenic animal products), in order to garner resources in the form of monetary and social support (Placek 2017). A study conducted among South Indian women lent support for this hypothesis by demonstrating that self-reported cravings for pathogenic and toxic foods were associated with a combination of factors that signaled a lack of resources in the form of social support and adequate access to food (Placek 2017).

Conclusion

The current leading hypotheses for both pregnancy aversions and cravings include maternal-fetal protection and resource scarcity. In addition to these, pregnancy cravings are explained by nutrient-seeking and social bargaining. Evidence of pregnancy dietary aversions and cravings suggest that in some circumstances, women target foods that provide protection and support during heightened periods of vulnerability, whereas in contexts of resource scarcity (in the form of either material or social), targeted foods might signal a need to diversify intake or garner additional support. Additional research is needed that simultaneously tests these hypotheses to tease out how environmental variability, cultural norms of diet, and trimester of pregnancy shapes women's preferences.

Food Dunking

Vicki K. Bentley-Condit

Synonyms

Food washing

Definition

The placement, dipping, or emersion of a food item in and out of water either before or during the consumption process.

Introduction

Food dunking is a relatively rare form of “borderline” or “proto”-tool use found among a few animal classes. It is primarily limited to Passeriformes within Aves and Primates within Mammalia, with a few exceptions among other birds and mammals. It is generally classified as “borderline” tool use (Bentley-Condit and Smith 2010) or proto-tool use (Morand-Ferron and Lefebvre 2007) rather than “true” tool use as a true tool is manipulated by the user while a borderline tool remains part of the substrate from which it originates (Bentley-Condit and Smith 2010). Thus, in dipping a food object into a water source, the food dunker does not control or manipulate the water even though the water is “used” to alter the food. In most cases, food dunking appears to be a food preparation technique. It is used primarily to either soften foods or to remove dirt or other substances such as toxins from a food item. Food dunking differs from bait fishing in that, in the latter, an item (sometimes food) is placed in the water specifically to attract a desired prey by the “fisher,” whereas in the former, it is the item placed in the water that is consumed. Some of the controversy surrounding food dunking lies not in the behavior itself but in what it means, i.e., whether it indicates animal “culture.” Food dunking has been observed under both wild and captive conditions for animals ranging from birds to great apes to suids.

The frequency and conditions under which food dunking occurs varies for both species and individuals and may involve a cost/benefit analysis. Food dunking may shorten the time it subsequently takes an animal to consume a food item, for example, when a dry object is softened, thus providing a benefit. However, the act of food dunking may be costly in that the animal may

need to transport the food item to a water source and devote more time to the item’s preparation or that, in doing so, the food item may be more likely to be stolen (Morand-Ferron and Lefebvre 2007).

Food Dunking by Birds

Morand-Ferron et al. (2004) report that food dunking by birds has been observed in the wild in more than 25 species. In most cases, the birds appear to be removing dirt or toxins, softening a hard item, or occasionally smoothing the fur or feathers of a prey item to make it easier to swallow. Birds will dunk food items including, but not limited to, frogs, eggs, hard bread, and insects. Dunking may also be a method to provide water to nestlings in areas where water is in short supply (Koenig 1985). More rarely, dunking is used to actually drown prey. However, in these latter cases, it is debatable as to whether or not this actually represents “dunking” as opposed to “predation.” What we see most consistently is the softening, cleaning, or facilitating swallowing functions of the behavior among birds. As well, the majority of the reports of food dunking among birds are anecdotal. However, Morand-Ferron et al. (2004) and Morand-Ferron and Lefebvre (2007) have conducted numerous field-based experiments to investigate these behaviors in the Carib grackles of Barbados.

Food Dunking by Primates

One of the most well-known examples of food dunking among primates is the “sweet-potato washing” practiced by Japanese macaques (*Macaca fuscata*) on Koshima Island in Japan (Hirata et al. 2001). The washing initially spread among playmates (the first one to perform this food dunking was a juvenile female named Imo) and then from younger to older individuals between 1953 and 1959. After 1959, it spread primarily from mother to offspring as it had become established in almost 80% of the younger adult monkeys. Since those early observations, the Koshima Island monkeys have continued to

dunk and wash sweet potatoes across the generations (Hirata et al. 2001).

Food dunking, or washing, has also been reported among captive capuchin monkeys (*Cebus apella*), crab-eating macaques (aka, long-tailed macaques; *Macaca fascicularis*), and great apes (Allritz et al. 2013; Visalberghi and Frigaszy 1990) and by free-ranging Japanese macaques at Katsuyama, Japan (Nakamichi et al. 1998). Items dunked/washed ranged from apples to grass roots. More recently, the long-tailed macaques of Nom Sao Island, Thailand, have been observed to wash the fruits of prickly pear cactus as part of the spine-removal process (Tan et al. 2016).

Food Dunking by Other Mammals

Food dunking by mammals other than primates is much more rare. It has traditionally been reported for raccoons (*Procyon lotor*), but, in reality, raccoon food washing appears to be an artifact of both captivity and the fact that raccoons forage in water and handle their food as part of the evaluation and identification process (Lyll-Watson 1963). Thus, they are not technically dunking food items in order to clean or soften them. However, captive North American river otters (*Lontra canadensis*) wash their food in order to remove dirt and debris (Neunteufel 2007), and recent data regarding captive Sulawesi babirusa suids (*Babryrousa celebensis*) and European wild boar (*Sus scrofa*) indicate that they do as well (Sommer et al. 2016; Ito et al. 2017).

Conclusion

In conclusion, food dunking is a relatively rare form of proto-tool use found primarily among Primates and Passeriformes in which a food item is submersed as part of the food preparation process. The behavior has sometimes been referred to as “pre-culture.” It is this aspect of food dunking that has been controversial, e.g., whether its existence is an indication of culture in other animals. While it appears to often represent the social transmission of a behavior – and sometimes

transgenerational continuity – whether that constitutes culture depends largely on how that term is defined and to what criteria we hold other animals. Whether or not it indicates culture, food dunking appears to be widespread within those populations/species that practice it.

consume a wide range of foods, which is evident in the great variability of diets worldwide. While omnivores or food generalists are not programmed for any specific diet, humans display universal tendencies such as an innate aversion to bitter tastes or fear of new foods – these preferences protect the organism from ingesting possibly dangerous items. Challenging this tendency for caution is the need to explore new edibles in order to vary the diet and prevent nutrient deficiencies. This conflict between an interest in novel foods and a fear of them is a dilemma with which omnivores must deal.

Human dietary predispositions

Definition

An overview of human dietary preferences, including innate predispositions to favor and avoid certain tastes as well as the role of culture and environment in shaping food preferences.

Introduction

Humans occupy a multitude of habitats on earth – a success possible due to our dietary flexibility, among other things. As omnivores – animals that eat both plants and other animals – we are able to

Omnivores and their Dilemma

For omnivorous species, taste is a crucially important sense: with a wide range of potential foods, one could face both nutritional benefits and dangers of toxin ingestion. The proper dietary strategy of our ancestors, Paleolithic foragers, would have been to consume small amounts of different foods to decrease impacts of toxins, pathogens, and poisons (Rozin and Rozin 1981). The need for dietary variety is hard-wired biologically (Rolls et al. 1982), and its goal is a balanced diet with an adequate range of micronutrients, as well as limited toxin ingestion (Remick et al. 2009).

The drive to explore novel foods leads to a conflict between neophilia (interest in and liking the unfamiliar) and neophobia (fearing and avoiding it), called the “omnivore’s dilemma” (Rozin 1976; Rozin and Rozin 1981). Neophobia is adaptive as it can protect against illness or death from poisonous foods, but it limits dietary variety, possibly causing deficiencies. Learning through experience, though, can override the fearful response to the new – a food first rejected can become a preference (alternatively, a negative experience can lead to rejection of the previously liked food item). Cuisine – a cultural system that defines edible foods and how to eat them – is another way to deal with neophobia, making every meal familiar and thus nonthreatening (Rozin and Barker 1982). Variety is additionally ensured with palate fatigue, a sensor-specific satiety that prevents one from fixating

on a food item and limiting the diet (Rollo and Marota 1999).

Innate Preferences Through Taste

Being able to taste is so important to an omnivorous eater that the taste system is the most durable of all sensory systems – the taste bud and gustatory epithelium (the taste organ) are one of the very few human organs capable of total regeneration (Fausto et al. 2012). An inability to sense flavors can lead to ingestion of rotten or poisonous foods with a potentially lethal outcome to the organism. There are five tastes detected by most mammals: sweet, salty, sour, bitter, and savory (or umami). While other nutrient taste qualities have been suggested, such as receptors for fatty acids, there is little agreement on whether they can be described as unique tastes yet.

The tastes of sweetness and its opposite, bitterness, display universal preferences with humans being quite fond of sweet tastes, while avoiding bitter ones. The preference for sweet foods is seen with both newborns and adults, who have an attraction to moderately strong sweet sensations. These preferences make sense as, in nature, most sweet foods are fruits and are thus easily digestible sources of calories. Over millions of years, these food sources of sweetness were rather limited, making the modern abundance of refined sugar a very recent and unusual event.

Moderately bitter tastes are rejected by newborns with an innate aversion. The human ability to taste, dislike, and avoid bitterness is considered adaptive, since many toxic compounds are experienced as bitter. Most naturally occurring bitter compounds are toxins at certain higher concentrations, and for stronger bitter tastes the body responds as if a toxin were about to be ingested (e.g., with vomiting). For weak bitter tastes, such a response is not present since normal foraging behavior would require some habitual intake of moderate bitter tastes. With a varied diet, various toxins contained in plants should not become problematic, as we would not ingest enough of them to cause harm. Besides, bitter plant compounds are often beneficial and have medicinal

properties (e.g., antioxidants). Bitterness is also experienced with free fatty acids in foods as they are involved in food deterioration – the ability to detect these may reflect an adaptation against eating spoiled foods containing oxidized fats (Drewnowski and Almiron-Roig 2009).

The ability to sense bitterness is a variable trait in humans, as there is genetic variation between populations in how sensitive they are to bitter taste. Specifically, people have been found to differ in their response to PTC – a bitter chemical phenylthiocarbamide. Half of the population is estimated to be tasters (able to taste PTC), 25 % are considered supertasters or those very sensitive to the chemical, and the remaining 25 % are classified as nontasters (Bartoshuk 2000). The receptors involved in this variation respond to plant secondary compounds (those made by the plant to be poisonous or unpalatable to predators), and supertasters with their high sensitivity tend to dislike vegetables containing such bitter compounds. These foods include many cruciferous vegetables like broccoli, whose secondary compounds can be beneficial for health.

Having moderate sensitivity to bitterness would seem like the best solution – one would avoid strong bitter-tasting foods yet still include health-promoting plants with low levels of natural toxins. However, being a nontaster could also be advantageous under certain conditions. Having such low sensitivity has been hypothesized to be protective for individuals living in endemic malaria regions of Africa, as some secondary plant compounds in the area have antimalaria effects. The protection from eating such bitter plants would outweigh the danger of poisoning (Soranzo et al. 2005). Nontasters are also less sensitive to strong spices, which could present another benefit – protection from microbial food contamination. Sherman and Hash (2001) analyze spice use in relation to ecology and show a pattern of increased spice use in hotter climates. This pattern is only true for spices that inhibit bacterial growth and only in dishes made with meat. Thus, cultural preference for spicy food appears to have risen due to their antimicrobial properties.

Lastly, our preferred tastes include salt and savory. Humans begin showing a preference for

a salty taste around 4 months of age, and moderate salt concentrations in food are highly attractive to us (Breslin et al. 1995). As humans lose salt through sweat, they prefer a higher intake of salt than other omnivores. The savory (or umami) taste is another important preference and is found in many cooked and fermented foods. Cooking and fermenting increase availability of glutamate, an amino acid for which humans have developed an affinity. The savory taste of glutamate could be a marker of protein content, though fresh raw protein foods are not in fact savory without the transformation of either heat or fermentation. Thus, fondness of this taste could suggest a preference toward easily digested proteins in cooked or slightly aged meats (Breslin 2013).

Food Palatability

The Maillard reaction – a chemical reaction responsible for browning and flavor production in foods when cooked – increases palatability of many foods (Maillard 1916). Cooked foods in general appear to be preferred to raw ones by humans, and every human culture cooks. We are not the only ones attracted to cooked flavors – great apes also inherently prefer cooked meat and starchy foods when a raw version is present (Wobber et al. 2008). Products of the Maillard reaction have both negative (e.g., carcinogenic, prooxidant) and positive (antiallergenic, antioxidants) impacts on health (Tamanna and Mahmood 2015), but we might have developed defenses against the dangerous byproducts. For example, acrylamide is toxic in mice and rats but appears less dangerous in humans.

Cooking does not simply increase palatability of various foods – it also would have provided omnivores with the most varied dietary choices, allowing us to diversify our diets to items that are toxic or indigestible when raw, in turn expanding the environmental range for human habitation. Because of universal reliance on cooking by all human cultures, Furness et al. (2015) even propose that humans should be classified not as omnivores but *cucinivores* – species with the dietary

specialization of eating cooked or otherwise prepared foods.

The fat content of foods also contributes to its enjoyment and palatability (Drewnowski and Almiron-Roig 2009). Palatability has a direct relationship to nutritional value with high-energy foods receiving higher preference, and fat – the most concentrated source of edible calories – is the reason palatability is so closely related to energy density (Drewnowski 1997). Children learn to prefer flavors associated with high-energy foods rather quickly and begin selecting fatty foods early in life (Birch 1992), as high-fat food items induce the least neophobia (Rankin and Mattes 1996).

Developing Preferences: Genes and Environment

Food processing through cooking, fermenting, and other techniques is an important element of human culture, and several examples illustrate the significance of these behaviors in the evolution of food preferences. Differences in the ability to digest starches are a prominent example of coevolution between genes and culture. The enzyme necessary to digest starchy foods – amylase – is produced in the pancreas by all mammals, but certain few mammals additionally produce it in the salivary glands, which predigests starches in the oral cavity. Humans are unique among these few mammals as we have a higher number of copies of the salivary amylase gene (AMY1). Agricultural advances over the past 10,000 years have increased reliance on starchy grains as staples, which appears to have resulted in increased AMY1 copies for societies with traditionally high-starch diets (Furness and Bravo 2015). AMY1 is not effective on digesting raw starches, however, so it has been proposed that cooking and increased AMY1 copies evolved simultaneously (Hardy et al. 2015), allowing starches to become important reliable sources of extra energy in the diet.

Another example of gene-culture coevolution affecting food preferences is lactase persistence into adulthood. For mammals in general and the

majority of humans, the enzyme lactase (necessary to digest lactose, a major sugar in milk) disappears after weaning. However, populations with a legacy of dairying have evolved the ability to digest lactose in adulthood – a trait that has evolved independently both in Europe and Africa in only about 7000 years (Tishkoff et al. 2007; Ranciaro et al. 2014). Development of dairy farming and consumption of milk products into adulthood correlates with the selection for genes that code for the persistence of lactase expression (Perry et al. 2015). Not surprisingly, lactase persistence is a common phenomenon in populations that have a long history of milk production: adult lactase expression is present in 75% of northern Europeans, yet only 5% of populations that hunt and gather in the same regions have it (Malmström et al. 2010). Ability to ingest dairy, as an energy-rich food high in nutrients and water (which would be important in arid climates), could have provided an evolutionary advantage.

Modern Food Environment: The Mismatch

Innate preferences for sweet and salty, as well as rejection of bitter tastes, do not predispose humans to pursue a diet currently recommended by many governments and health agencies – rich in plants yet low in sugars and sodium. The industrial revolution led to an abundance of highly processed and palatable foods. Such items feature not only high sugar, sodium, and fat profiles – a combination highly attractive to humans – but they also bypass sensory fatigue by presenting many flavor variations despite poor breadth of ingredients. One hundred years of rapid dietary changes would not have been enough for humans to adapt adequately in only a few generations (Carrigan et al. 2015). Modern health problems related to these novel processed diets – such as obesity and diabetes – also would not be selected against, since the dietary conditions that facilitate them are so recent in evolutionary history. The dramatic recent rise of these noncommunicable conditions may be due to the evolutionary

advantage of having thrifty genes, which increase efficiency of fat storage yet predispose one to chronic disease. According to the “thrifty genotype” hypothesis (Neel 1962), having a large appetite and rapid energy uptake was advantageous in the past, as these traits would have been selected for to deal with feast and famine periods. Such thriftiness would however become harmful in a time of plenty with easy access to unlimited, cheap calories. This hypothesis, however, has received criticism and alternative ones have been proposed, e.g., Speakman (2008) suggests that the obese phenotype is due to genetic drift, not the positive selection of “thrifty” genes.

While human innate preferences appear problematic in the times of plentiful, inexpensive calories, they can be changed and reversed through learning. In addition to the genetic predisposition for certain tastes, humans also possess the predisposition to develop new preferences based on experience with foods – associating foods with context and consequences shapes and modifies preferences. We surely learn to enjoy tastes of some bitter foods like dark chocolate, coffee, and wine; we can also develop an aversion to a previously preferred food, such as after a food poisoning episode. In other words, flavors and tastes that become associated with energy and nutrients become preferred, while illness and poisoning cause associated flavors to be aversive – a process that is not necessarily conscious (Breslin 2013).

Conclusions

An omnivore’s eating strategy must account for two needs: to avoid poisoning and death and to ensure a balanced diet without nutrient deficiencies. The taste system plays a major role in ensuring the survival of an omnivore that faces limitless eating decisions. Our innate taste preferences guide this process by disliking and avoiding bitter foods – often containing toxins in nature – and preferring sweet, savory, and salty tastes that signal high caloric values. Sweetness is an indication of easily digested sugars, while savory tastes could indicate protein sources that have been cooked, thus being more digestible and safe

from foodborne bacteria. Differences in bitterness sensitivity might reflect important adaptations, such as lower sensitivity in malaria areas leading to higher ingestion of bitter protective plants. Lastly, the coevolution of culture and genes has resulted in the importance of dairy and starches in human diets, as the evolving ability to digest them would have provided an advantage to those who could make these energy-rich food sources a reliable part of their diet. These human food preferences appear maladaptive in the current environment, characterized by access to highly palatable and energy-rich foods, yet they can be modified with learning in order to prevent health conditions associated with overnutrition.

eat itself, to another individual. It includes active donation of food but also tolerated theft.

Introduction

Feeding on food that it has foraged is of great importance to ensure the fitness of an animal. Giving up this food for a conspecific is thus one of the most prominent examples of altruism.

Although it may bear immediate costs for the donor, sharing food may however be beneficial on the long term. There are various examples of food sharing in the animal kingdom, most of which can be explained by mechanisms such as kin selection or reciprocity (Stevens and Gilby 2004).

Food Sharing and Nonhuman Reciprocal Altruism

Karin Schneeberger
University of Bern, Bern, Switzerland

Definition

Food sharing is a form of altruism, during which an animal gives up food, which it could otherwise

Mechanisms and Examples of Food Sharing

Food sharing has been extensively studied in various species. In social carnivores, for example, active food sharing is rare, but passive sharing i.e., allowing conspecifics to feed from the same carcass at the same time, is common (reviewed in Feistner and McGrew 1989). Some carnivores such as African wild dogs (*Lycaon pictus*) and wolves (*Canis lupus*) regurgitate food for pups. This type of active food sharing is mostly driven by kin selection, as members of the family predominantly show this behavior, such as older siblings for the younger ones (Malcolm and Marten 1982). Through kin selection, an individual gains fitness by helping a conspecific sharing proportions of the same genes and thus promote the representation of these genes in the gene pool of the next generation (Hamilton 1964).

However, African wild dogs unlike other carnivores also regurgitate food for adult pack members, both related and unrelated. Thus, where kin selection can not explain why an individual may give up food for a conspecific, Stevens and Gilby (2004) suggest other mechanism to maintain such altruistic behavior in a population. Young ravens (*Corvus corax*) for example may inform other individuals about the location of food through recruitment calls (Heinrich 1988). In groups,

they are able to overwhelm otherwise dominant adult territory holders and thereby gain access to carcasses they could not get on their own. Thus, by sharing food, they gain immediate benefits through increased foraging success. Other immediate benefits occur when food is provisioned to mates (nuptial feeding), as in many arthropods (Gwynne 2008), or by reducing aggressive behavior of an opponent, such as in primates (Stevens 2004).

In other cases, there are no obvious immediate benefits for the donor. One of the most prominent examples of nonprimate food sharing is the one by common vampire bats (*Desmodus rotundus*; Wilkinson 1988). Vampire bats feed on blood of large vertebrates and heavily depend on successful foraging trips, as an otherwise starving individual would die within a few days. As most other bats, vampires live in large colonies of both related and unrelated individuals. Successfully foraging vampires have been observed to regurgitate blood for unsuccessful conspecifics and thus save them from starving, a behavior which is reciprocated, mostly in dyads (direct reciprocity). While food sharing in this case does not have large negative consequences for the donor, it is of tremendous value for the receiver, and thus there is a net benefit for food sharing dyads. Besides food-for-food, vampire bats also seem to share food for grooming (Wilkinson 1988). Thus, as other altruistic services, food may be traded against other commodities, which is frequently the case in primates (Jaeggi and Gurven 2013), where food is exchanged for grooming, support during conflicts, and access to mates. Furthermore, sharing food with conspecifics can enhance the overall status of an individual within a group or lead to overall benefits for the group such as increasing group size and thus survival of group members (Stevens and Gilby 2004).

While food sharing in nonhuman animals is frequently enforced by harassment, much human sharing is voluntary and proactive (Jaeggi and Gurven 2013). It is widely observed across populations and attributed to various functions: By sharing high quality food, men could enhance their status as good hunter in a group, and thus increase reproductive success. However, women

also frequently share food, for example, as part of a sexual division of labor which increases foraging efficiency and thus family provisioning. Food sharing among nonrelatives overall increases social status in humans and recruit support for times in need. Furthermore, investing in social capital through contributing to public goods may buffer the risk of unpredictable foraging success in the future. As in other species, reciprocity may play an important role in human food sharing among nonkin, as giving and receiving food seems to be highly correlated across human populations.

Conclusion

Food sharing is one of the most common forms of altruism. Although it is costly in the first place, it may as well have short- and long-term benefits for the donor. As during other altruistic acts, food may be exchanged for other commodities, such as social support or mating opportunities, and thus be part of a complex social behavior network.

Definition

Aggressive tactics that are used to overcome mating resistance.

Forced Copulation

Forced copulation, also referred to as *forced mating*, is when aggressive tactics are used, typically by males, to overcome mating resistance. This term is typically used to describe unwanted copulation in nonhuman species, whereas the term *rape* is reserved for humans. *Resisted mating* describes unwanted copulation in species where female resistance and male use of force is the most common form of mating. In these species, resistance may function by indirectly or directly “choosing” a dominant male (Lalumière et al. 2005). Forced copulation is different from resisted mating because it occurs in species where aggressive tactics are only sometimes used to circumvent female choice for preferred mates. Females in these species are receptive to preferred males

and unreceptive to non-preferred males or are unreceptive during non-preferred times. Males who use force to copulate are non-preferred or pursue copulation during a non-preferred time.

Unlike other forms of sexual coercion, such as harassment (i.e., persistent sexual pursuit until the female capitulates or flees) or sequestration (i.e., aggressive removal of a female from her social group), forced copulation describes direct, aggressive attempts to mate. Female resistance to male sexual advances includes fleeing, resisting, avoiding genital contact, and forceful attempts to heave or fling a mounted male. Actions by the aggressors include pursuing, surprising, grasping, restraining, and biting, many times resulting in injury. In some species, there are physical or physiological traits that appear to assist with forced copulation, such as the notal organ in *Panorpa* scorpionflies, which is used to grasp females (Thornhill 1980).

Forced copulation may have evolved as a sexually dimorphic adaptation, functioning either as a facultative or obligate trait. Forced copulation is facultative when coercive mating depends on certain environmental circumstances (e.g., in American black ducks *Anas rupribes*, males force copulate in response to cuckoldry risk) and can either be flexible (propensity to engage in forced copulation is flexible across the lifespan) or fixed (propensity to engage in forced copulation is generally fixed after a certain point in development). Forced copulation is obligate when sexually coercive males are genetically different from males who are not sexually coercive (e.g., in pygmy swordtail *Xiphophorus nigrensis*, males who engage in sneaky copulation are genetically different from males who do not engage in sneaky copulation). For more examples and details, see Camilleri and Stiver 2014; and Lalumière et al. 2005. Forced copulation is studied as a form of sexual conflict, where an adaptation in one sex (forced copulation and/or mating resistance) comes at a cost to the other sex (see ► “Sexual Conflict”).

Lalumière and colleagues (2005) identified five conditions under which forced copulation has been observed: (1) the *circumstantial opportunist* – species that do not form pair bonds and

males force copulate when faced with an unreceptive female; (2) the *opportunistic spouse* – species that form pair-bonds and males sometimes pursue extra-pair copulation through forced mating; (3) the *cuckold* – species that form pair-bonds but males sometimes force copulate one's mating partner, typically in response to cuckoldry risk; (4) the *competitively disadvantaged* – species where males resort to forced copulation when they are not preferred by females due to having poor health, few resources, or lower dominance; and (5) the *morph* – species where males who pursue forced or sneaky copulations are genetically different from males who do not pursue such tactics. Some forms of forced copulation may not be adaptive but may result as a byproduct of other adaptations (e.g., Davian behavior) or as a disordered adaptation (e.g., paraphilias).

Forced copulation is observed across many insects, fish, reptiles, and mammals. Recommended in-depth reviews of forced copulation, and sexual coercion more generally, among nonhuman animals can be found in Camilleri and Stiver (2014), Clutton-Brock and Parker (1995), Lalumière et al. (2005), Muller and Wrangham (2009), Smuts and Smuts (1993), and Thornhill and Palmer (2001).

What are the different ways of caring for children who are not one's biological children?

Introduction

On the surface, adoption is something of a paradox from an evolutionary perspective as it appears to run counter to the evolutionary principle of passing on copies of one's own genes as one instead invests time and resources into other people's offspring (Hamilton 1963). However, adoption is nearly ubiquitous across known cultures, suggesting that it might have some evolved component (Silk 1990; Volk 2011). What is noteworthy about adoption is the variety of forms it can take. These forms are tied closely to cultural norms and the functional outcomes of adoption preference. There are two main forms of adoption, based on whether one is adopting an unrelated child or a related child.

Adopting Related Children

Evolutionary theory suggests that parents should invest in related children so long as the cost to themselves (i.e., their own genes) is offset by the benefit to the shared genes in the related children (Hamilton 1963). So from a crude evolutionary point of view, it is worth sacrificing one-fifth of one's time and energy to raise a niece or nephew who shares one-fourth of one's genes. Thus the degree of support provided to adopted children in this context likely depends on how closely they are related (e.g., a niece versus a second cousin) and how costly the investment will be to the adopting parent(s) (e.g., if they don't have any children of their own, then the costs will be lower and the benefits greater; Rawson 2003). Even in modern contexts where the primary motive is altruistic parental substitution, the success of an adoption is based on kinship networks of support (Johnston 2012), highlighting the role of kin in any adoption process. The critical role of human non-parents as alloparents who support the upbringing of most children (Hrdy 2009) makes it

a very small leap from many adults providing some alloparental care to some alloparents providing all of the parental care (i.e., adoption or fosterage).

The most likely circumstances for this form of adoption are when one or both of the parents die (Halbmeyer 2004), a not uncommon event in the evolutionary past (Volk and Atkinson 2008). Particularly in an evolutionary context, children without their parents (and especially without their mother) face greatly increased levels of mortality (Sear and Mace 2008). Under these circumstances, the related adopting parent functions enable the survival of the related child (a large benefit) for a relatively modest cost (a smaller cost than birthing and raising one's own child – particularly if the child is older). This is likely a relatively ancient pattern of behavior (Hrdy 2009) as chimpanzees have been observed to adopt younger siblings if they are maternally related (Hobaiter et al. 2014).

Further, in humans, this function of adoption is not limited to orphaned children as it may also apply to children whose biological parents lack the mental, emotional, and/or economic means of caring for them (Volk 2011). This pattern is commonly observed in fosterage systems (caring for the child of a living parent) where children are placed in the care of a related individual (Scelza and Silk 2014). In North America, just under half of all adoptions are by kin who are supporting children with a living parent (Stolley 1993), while 31 % of fostered children are raised by kin (Testa 2004). These numbers might as well be higher as many families rely on informal systems of adoption and fosterage to support ill-equipped biological parents. This too is a relatively ancient practice, as it is fairly widely practiced among hunter-gatherers and agriculturalists (Alber et al. 2010; Silk 1990; Volk 2011). It was also extensively practiced in the seventeenth-century Europe when poor parents gave up their children to wealthier relatives with the hopes of eventually being able to reclaim them under better economic conditions (Cunningham 2005). Similar practices were common in Brazil until recent times, leading to tragic modern scenarios where some mothers give up their children for others to raise only to find that when their economic circumstances have

improved, the government no longer allows them to reclaim their children (Fonesca 2004). Overall, these patterns of kin adoption or fosterage allow broader family networks to adaptively pool their resources in order to optimize their investment in the next generation.

Perhaps the most dramatic example of kin support fosterage comes from the Baatombu of Northern Benin. Traditionally, almost all Baatombu children were raised by relatives other than their biological parents (Alber 2003; Alber et al. 2010). Boys were raised by male relatives and girls with female relatives, with the father's side of the family getting the firstborn, the mother the second, etc. (Alber 2003). Interactions between the birth parents and their children were strongly discouraged in order to maintain the adopted kin structure. The Baatombu believed that this served two important purposes. First, it promoted child survival by ensuring that only adults with sufficient resources were entrusted with raising a child. Second, it promoted within-family solidarity by reinforcing the kin network by sharing its most precious resources – their children. So a process of kin selection is reinforced not only by increased child survival and thus shared genetic transmission but also by using adoption to build stronger familial social networking.

Adopting Unrelated Children

From an evolutionary perspective, the adoption of unrelated children is not immediately adaptive as one is not invested in the transmission of shared genes to future generations (Hamilton 1963). To get around this evolutionary issue, parents who adopt unrelated children have relied on a variety of motives. Some are adaptive, while others may be the unintended by-products of adaptive behaviors and motivations.

Altruistically Motivated Adoption

The most widely familiar modern function of adoption is as an altruistic substitution for biological children, typically due to infertility or

child mortality (Volk 2011). Under these circumstances, parents are strongly motivated by a (potentially innate) desire to raise children but do not have any biological children of their own to whom they can apply this motivation. In modern society, such parents are typically of Western descent and are wealthy, educated, older (late 30s to early 40s), and highly motivated to care for a child (Hamilton et al. 2007). The adaptive function of this behavior is questionable as it typically does not translate into the transmission of one's genes. Indeed, adoption is often a very costly affair for the adopting parents (Cunningham 2005; Howell 2006). Instead, it may represent a mismatch between an adaptive, evolved desire to have a biological child and the inability to do so. Humans appear to be one of, if not the most, parental care-oriented primates (Hrdy 2009), so it is not terribly surprising that the motive to care for children leads some adults to engage in maladaptive behaviors. The strength of this motivation is such that it may even result in caring for offspring of other species (Riedman 1982; Vining 2003). Thus, the selfish desire to invest in one's own genes can be overcome, in some cases, by the evolved desire to care for younger members of one's own, or of even a different, species (Volk et al. 2007). In other cases of adopting non-kin, the payoffs are more concrete.

Socially Motivated Adoption

Among some societies, childlessness is viewed as immoral, leading wealthy infertile women to choose to adopt an unrelated child to maintain the social structure of motherhood (Talle 2004). Failure to do so would result in social ostracism that could potentially impact an individual's survival. The urgency of this form of adoption is illustrated by the reality that sometimes this adoption occurs despite the protests of the biological mother, whose husband forces the exchange of their child for material gains (e.g., a cow; Talle 2004). This form of parental substitution may or may not be altruistically motivated given the social pressures associated with the decision. But

it does result in a more concrete benefit than does purely altruistically motivated parenting.

Another socially motivated form of adoption was the creation or maintenance of social alliances (Volk 2011). The general idea in this context is that if an individual raises another person's child, then the biological parent has a vested interest in the success and well-being of the adoptive parent as they are responsible for raising their biological child. Many native North and South American groups used adoption as a means of ending blood feuds as well as integrating captive children into their new groups (Volk 2011). Similar practices were observed among other violent hunter-gatherer groups that practice blood feuds (e.g., New Guinea highlanders). The practice was also quite common in historical cultures ranging from ancient Rome to medieval Europe to late Imperial China (Cunningham 2005; Hsiung 2005; Rawson 2003; Volk 2011). In all of these cases, kin selection was used as a tool for both reducing tensions and violence between groups and promoting new social networks by offering one's children as a guarantee for one's social cooperation and against one's use of violence. Ancient Romans also used it as a means of spreading their cultural values. By raising the son of a conquered chief, that adopted son could then be used as a cultural liaison with their former tribe once they were adults to promote the interests and values of Rome (Rawson 2003).

A final form of socially motivated adoption is its use as a means of fostering marriage arrangements (Volk 2011). This can either be through exchanging children who are to be later married or by adopting a child who is meant to serve as a future wife when they are older (Halbmayer 2004).

Economically Motivated Adoption

This form of adoption is generally not present in modern Western cultures, but it is relatively common in other cultures and earlier in Western history. It involves the adoption of unrelated children in order to gain economic resources or labor. Historically, child abandonment was the basis

for a form of economic adoption whereby either wealthy individuals could adopt found children as slaves (Rawson 2003) or institutions could be set up to receive money for raising orphans (i.e., founding institutions; Cunningham 2005). The economic benefits to the participating adults are clear in either case, but both typically represented very costly forms of care for children who suffered from much higher levels of mortality (up to 90% in some cases) at the hands of economically motivated strangers (Cunningham 2005).

Evolutionarily speaking, a more common form of economically motivated adoption was for known individuals (e.g., members of a village) to exchange children in return for economic benefits. In the case of resources, children are valued primarily for their current and/or future capacity for labor. A typical example would be for economically poor biological parents to exchange their child for resources with wealthy and/or elderly fostering parents (Kirkpatrick and Broder 1976). The benefit to the latter would be the free labor provided by the adopted child. While this is to a degree, a form of childhood servitude, most cultures enforce rules on how adopted children are to be cared for and treated (Talle 2004; Testa 2004). If the adopting parents violate these rules, then the biological parents can cancel the contract and reclaim their child. Thus, it is typically a reciprocal agreement whereby poor biological parents get much needed resources and are relieved of the costs of raising a child, while wealthy/elderly adopting parents are able to translate material resources into labor outside of a free-market economy.

However, there are some potential variations to this theme. For example, among the Ifaluk of the Western Caroline Islands, wealthy individuals give away their biological children to poorer adopting parents (Betzing 1988). This does not appear to be a form of reciprocal altruism. Rather, it appears to be an effort by elites to translate their economic and social power into parasitic brooding. That is, the biological parents force less powerful adopting parents to bear all of the costs of raising the adopted child without offering any benefit in return. While perhaps morally dubious, this does offer powerful individuals a means

of increasing their potential reproductive success by dramatically passing off the costs of raising their biological offspring to unrelated individuals.

Conclusion

Adoption is a flexible tool that can serve one or both functions within or outside of family networks. From an evolutionary perspective, there appears to be a gradient of parental care from raising one's own children to investing in related kin (alloparenting), to raising kin (adoption), and to raising unrelated children in exchange for altruistic, social, and/or economic benefits. The sheer versatility of the functions adoption and fosterage suggests it is an ancient and fairly ubiquitous means of promoting individual and familial evolutionary fitness. It is ironic that the most familiar form of adoption in modern Western society is perhaps the least evolutionarily motivated and viable function of adoption (altruistic parental substitution). Yet it is perhaps the most socially altruistic expression of the evolved human desire to protect, care for, and spend enormous time and emerging raising biologically unrelated relatively helpless infants and children. Nevertheless, it is important to recognize that adoption is a highly varied behavior whose form and function can vary widely between individuals, cultures, and time periods.

Fostering Values of Fairness

Definition

The processes by which evolution can design cognitive mechanisms equipped with certain assumptions about what counts as fair.

Introduction

Because natural selection designs phenotypes that favor the replication of the genes that built them, contemporary evolutionary theory predicts that organisms should be strongly biased toward their and their kin's own interest. However, in some species, including humans, the complexity of social life has led to the emergence of values that are not exclusively aligned with self-interest.

It is widely agreed that among these values is a concern for fairness. But what counts as fairness to the human mind? Depending on circumstances, it can refer to a number of different things. As an example, what is a fair division of the spoils of a hunt among the members of the hunting party? Several criteria are possible, some of which might conflict with each other: one is equal division between the members, another is a division proportional to each party's contribution to the hunt, yet another is a division that is proportional to their need. "Fairness" has also been used to describe the impartiality of a procedure (regardless of its eventual outcome) or even a general concern for others.

Norms of fairness and their influence on human behavior have been extensively studied by psychologists and economists. Because of their diversity, they raise several issues that evolutionary theorists have recently focused on.

Explaining Deviations from Selfishness

Human behavior in a number of economic games deviates from the standard economic model, which sees agents as rational and self-interested. For instance, in a task called the dictator game, players are given a sum of money and may choose to share part of it with another player; their decision is anonymous. In contrast to the self-interested model, a substantial portion of players choose to share some of the money. This and other "anomalous" results have been taken to show that humans are averse to inequality (Fehr and Schmidt 1999). Furthermore, developmental work suggests that humans develop a sensitivity to distributive justice from an early

age: as an example, Geraci and Surian (2011) have shown that 16-month-old infants prefer looking at events in which resources are divided equally between recipients. A concern with equality raises the question of why people do not care solely about their own interests instead.

One explanation of these moral concerns is that humans are not in fact designed to look for their own interest. In models of cultural group selection, coevolution between genes and culture give rise to institutions that promote behavior for the good of the group and curtail selfishness: groups in which such institutions are prevalent outcompete other groups, causing the propagation of the institutions (Henrich et al. 2010). Although group selection models can explain generosity, they have trouble explaining why individuals would be opposed to inequality, a concern that sometimes leads to nonoptimal allocation, or even destruction, of resources and hence runs against the greater good (Shaw 2013).

Hence, most evolutionary theories explain instances of human selflessness by showing that they ultimately lead to individual benefit in the long run. These attempts focus on mutualism: in some situations, it is beneficial for both parties to interact with each other. For instance, parties in a trade benefit from the interaction, because otherwise they wouldn't take part in the exchange. In such cases, it is in the interest of an individual A to manipulate a current or potential interaction partner B so that B takes part in the interaction; often the best way to do this is to ensure that the interaction is beneficial to B. In Trivers (1971) model of reciprocal altruism, individuals are ready to suffer a cost to help another organism, if by doing so they increase the likelihood that the latter will help them in return, in a logic that can informally be described as "scratch my back and I'll scratch yours."

Recent work has extended this framework to take into account the possibility of partner choice, where people compete with each other to attract interaction partners. In the ultimatum game, a proposer offers to divide an amount of money between a responder and himself. If the responder agrees to the division, it is paid out, but if he refuses, both players get nothing. While

standard game theory predicts that the proposer offers the minimal possible nonzero amount to the responder and the latter accepts, André and Baumard (2011) show that the outcome is different when players are allowed to choose who they want to play with. In versions of their model in which it is easy to choose one's partner, evolution favors proposers who divide the resource almost equally between the responder and themselves, because by doing so they attract other players and get to take part in a greater number of beneficial interactions. When partner choice is harder, proposers can afford to make lower offers. Under this framework, what constitutes a "fair" offer is thus determined by the parties' relative bargaining power. Related game-theoretic considerations suggest that evolution should favor individuals who distribute a resource in proportion to each individual's contribution to its production, because productive individuals are more valuable partners and have better outside options. Indeed children as young as 3 years old display a tendency to distribute goods according to individual contributions (Baumard et al. 2012).

As noted above, an everyday-life example of mutually beneficial interaction is economic exchange. Behavioral economists have collected ample evidence that people have strong concerns for fairness in this domain. Kahneman et al. (1986) have shown that people object to increases in prices if they are not motivated by similar increases in production costs: it is unfair for a store owner to increase the price of snow shovels to take advantage of the increased demand caused by a snowstorm. In line with the idea that fairness norms are shaped by the parties' relative bargaining power, Friedman (2004) has proposed that this phenomenon is caused by a fundamental asymmetry of information in the relationship between buyers and sellers: while the buyer knows his reservation price (the maximum price he is willing to pay for the good), it can only be guessed by the seller. Therefore, the buyer can pretend that the current price of a good is very close to his reservation price and credibly threaten that he will not buy in case of a price

increase. Because trade of goods or favors was common in man's ancestral environment (e.g., food vs. help in intragroup conflict), such commitment strategies might have evolved in this context.

The Puzzle of Impartiality

Mutualistic accounts explain why people hold values that go beyond their own self-interest, but they do not explain why fairness is often characterized by impartiality. If people preferentially care about the welfare of individuals they can have beneficial interactions with, then they should exhibit favoritism toward them. By contrast, Shaw (2013) reviews data showing that strong impartiality is an important part of human values. People sometimes value impartial individuals over individuals who treat them preferentially: for instance, children preferred a distributor who distributed four erasers equally between the subject and another child over a distributor who gave all four items to the subject. Accordingly, people strive to be impartial, even if achieving that goal means discarding resources: people imagining themselves in the role of an employer refused to give a pay raise to an employee if it was not accompanied by a raise to his equally hardworking colleague. Shaw conjectures that selection pressures related to coalitional dynamics gave rise to this concern for impartiality. In a social species, the existence of alliances might have a negative impact on outsiders, giving the latter incentives to curtail the formation of new coalitions. Punishing partiality is one way to achieve this goal, and the potential for such punishment might then encourage people to appear impartial. That people are motivated to appear impartial, rather than intrinsically valuing impartiality, is supported by experiments showing that they are less concerned with fairness when their behavior is not made public (Shaw 2013).

More generally, in an interaction between two individuals, A and B, A's interaction with another

individual C matters to B, because it contains useful information. In the example of an economic transaction, in which B buys a good from A, B does not have full information about A's reservation price, but observing A selling the same good at a lower price to C gives her information about A's reservation price (namely, that it is lower than what A currently charges B), allowing her to bargain for a better deal. Indeed, people react with outrage when they learn that someone else pays a lower price for the same good or service (Kahneman et al. 1986). Therefore, impartiality can be a means of concealing strategic information. This has broad consequences, because such strategic information can also be exploited by third parties (agents exterior to the transaction), who might be motivated to punish an ungenerous individual in order to signal that they expect better treatment from him if they happen to interact in the future, or to avoid him altogether (Krasnow et al. 2012).

Conclusion

Empirical data shows that humans hold certain early-developing, complexly patterned moral values, which point to the existence of a biological sense of fairness. There is no clear consensus yet about the exact way by which natural selection has implemented these values in us, but an emerging body of theoretical work has tackled the challenge. Fairness cannot simply be equated with generosity, and the complexity of human intuitions about what constitutes fair behavior provides a fascinating benchmark against which to compare evolutionary models.

As theories of natural selection acting at the individual level suggest (e.g., Trivers 1971), moral values might not have evolved for the good of the group. Although a concern for fairness can mitigate the negative impacts of self-interested behavior on the greater good, it also has the potential of canceling some its positive impact: for instance, by disrupting the normal operation of supply and demand, it can cause markets to fail to clear,

resulting in a nonoptimal distribution of resources (Kahneman et al. 1986). Whether and how we as a society choose to foster the taste for fairness that nature has endowed us with depend on what we ultimately consider to be desirable, and careful considerations of the consequences of our intuitive preferences.

Definition

Evolutionary psychology is a psychological science where hypotheses are informed by evolutionary theory (especially middle-level theories, such as Trivers' parental investment theory or life history theory, see Buss 1995), as well as a consideration of known features of the species' relevant evolutionary past, i.e., relevant selection forces. In addition, there is a specific model of mind, where one considers the mind made up of a mosaic of mental mechanisms. This form of modularity follows Pinker's (1997) definition where modules are only partially informationally compartmentalized, not Jerry Fodor's more informationally encapsulated definition, as the modules are partly interacting and partly informationally encapsulated. These mechanisms are designed through natural, social, or sexual selection. They are context-dependent and process information according to specific rules as selected for. This may by many be called the Santa Barbara school of evolutionary psychology, but that specific approach has been somewhat broadened by a greater interest in sex differences and individual

differences during the last decades. Founders are those who contributed to the formation of the psychological evolutionary research program as it may be recognized today, especially as opposed to other evolutionary research programs within human behavioral science such as human behavioral ecology or gene-culture coevolution. Founders presented in the following include John Tooby and Leda Cosmides, Margo Wilson and Martin Daly, and David Buss. These were historically the five scholars who worked on the very first "Foundations of Evolutionary Psychology" at Palo Alto.

Introduction

Evolutionary psychology was founded in the 1980s, developed into a comprehensive and burgeoning field during the 1990s, and slowly became an integrated part of psychology in general the last 20 years. Considering the foundations of evolutionary psychology therefore warrants a look at papers written during the 1980s and the early 1990s, as well as work that has influenced the field the last 30 years.

There are three major research labs/groups that may be recognized as foundational and will be considered in greater detail in this chapter, although they all met at Harvard: John Tooby and Leda Cosmides, founding directors of the Center of Evolutionary Psychology at the University of California at Santa Barbara; Margo Wilson and Martin Daly, McMaster University, Canada; and David Buss, at Harvard, University of Michigan, and the University of Texas at Austin in charge of the evolutionary psychology and individual differences graduate program.

The current chapter will provide a brief introduction to some of the most influential contributors to the formulation and foundation of mainstream evolutionary psychology (EP). This research program was developed through more or less formal meetings over several years, but was most clearly formulated by John Tooby and Leda Cosmides as what is sometimes referred to as the Santa Barbara school. Parallel to Tooby and Cosmides' empirical work, Margo Wilson and

Martin Daly published large studies based on basic EP principles. The major communicator of EP within academia is probably David Buss, who in addition to large empirical studies also added a focus on sex differences to the mainstream EP research program, as well as personality and individual differences. While many more researchers – both independent and collaborators of the aforementioned – have also contributed to mainstream modern EP, this chapter will be restricted to the basic contributions of these five founders.

Evolutionary Psychology Is Not Sociobiology

Historically, evolutionary psychology is obviously not the first evolutionary approach to behavior, psychology, or human nature. In *Origin* Darwin is often quoted as pointing out that he believes that “In the distant future I see open fields for far more important researches. Psychology will be based on a new foundation, that of the necessary acquirement of each mental power and capacity by gradation.”

This is an interesting quote, but from a historical perspective, it is important to note how early this was in the development of any scientific psychology. Certainly Darwin’s work on human emotions is one of the first works on human psychological features from an evolutionary perspective, and he is also one of the first developmental psychologists with his observational study of his own child published in *Mind*. Pioneers such as William James and Sigmund Freud also were famously interested in phylogenetic musings and speculation. Prominent mainstream theorists such as John Bowlby and Mary Ainsworth were explicitly evolutionary, despite many current attachment scientists downplaying the evolutionary foundations of their classical theoretical work. Within anxiety theory, mainstream clinical work has always been based on an appreciation of the evolved functional underpinnings (Kennair 2007; Marks and Nesse 1994). However, none of these previous evolutionary approaches to behavior or psychology were part of an organized theoretical framework or research program. The most influential approach to human evolved behavior prior to the advent of evolutionary psychology was human sociobiology, strongly

influenced by E.O. Wilson’s popular work on sociobiology, heralding the use of recent theoretical developments in evolutionary biology to investigate behavior in animals, including humans.

It is important to note at this point the difference in considering manifest behavior versus considering the underlying evolved mental mechanisms. Dennett suggested that EP is merely the marriage of sociobiology with cognitive science. This might not fully appreciate the complexity of focusing on the adaptation as a cognitive structure (Kennair 2002). Once one accepts mental mechanisms as the relevant object of study, something behaviorists such as Wilson was hesitant to do, this affects both methods and how one implements theory in generating hypotheses. First, one stops primarily counting babies; that is, one stops to primarily consider current selection or adaptiveness. Don Symons was dismissive of evolutionary oriented scholars who sought a psychologically agnostic science, where humans are fitness maximizers. Cosmides and Tooby (1987) provide the link between manifest behavior and evolutionary science: the evolved psychological adaptation.

It takes time to construct human mental mechanisms through selection. Human universals, and thereby the cognitive underpinnings of our human nature, have to have been in place before humans migrated out of Africa. It is therefore not necessarily our current environment we are adapted to, but rather the relevant selection forces that were stable enough across deep time to design the mental mechanisms that make up universal human nature. Environments change faster than selection can form adaptations, especially when species migrate as far as humans have. Such mismatch makes it less relevant to consider current adaptiveness, but predictable output from hypothesized mental adaptations may be studied, and design features may be discerned based on such output.

While sociobiology considered current adaptiveness and built upon a behaviorist psychological model that studied behavior in current environments, evolutionary psychology predicts that mental mechanisms have been formed over

evolutionary time due to middle-level evolutionary theory and available knowledge about the relevant selection forces (EEA). Evolutionary psychology thus focuses on adaptations and is inherently founded on a mainstream social-cognitive psychology model of mind. This shift made evolutionary psychology more relevant for mainstream psychological science. In summary, where sociobiology was founded on the psychological theory of behaviorism, which studied observed behavior and considered whether this was currently adaptive, evolutionary psychology was founded on mainstream cognitive theory, which studies the results of mental processing and considers the underlying evolved mental adaptations.

Basic Evolutionary Underpinnings

Dawkins has had a great influence on EP through his synthesis of how selectionist reasoning and the new (in the 1970s) theories of behavioral and social evolution by Hamilton (1964a, b) and Trivers (1972, 1974) might be implemented in research. George Williams also provided fundamental insight, through the focus on formal criteria of the adaptation. It is important to note that the field also in general clearly identifies with Williams' refutation of group selection and his focus on the adaptation. From an evolutionary psychology perspective, group selectionist models are moot. Thus evolutionary psychologists in general take a Darwinian, gene level selectionist approach, focusing on inclusive fitness and middle-level theories (i.e., Trivers 1972) or specific versions of these (i.e., sexual strategy theory, Buss and Schmitt 1993) that may generate testable hypotheses and predictions (Buss 1995; Ketelaar and Ellis 2000).

In addition to focusing on identifying mental adaptations and using middle-level theories, an evolutionary psychology approach builds on what is known about the species' relevant evolutionary past: the relevant selection forces or the environment of evolutionary adaptedness (EEA). Knowledge about selection forces may suggest how specific traits could be shaped today. The combination of these two aspects provides the evolutionary basis of evolutionary psychology hypothesis and prediction generation.

At this point it may also be important to note the following: Evolutionary psychology is not a comparative approach, like sociobiology often was. Other species have had species-specific selection that has formed the adaptations that define those species; the same is true for human evolution. Considering what model species to choose when attempting to consider either warfare or sexual behavior is hard enough; chimpanzees and bonobos are both related to humans to an equal degree, but differ dramatically in those two specific areas. Furthermore, many of the most interesting human psychological phenomena are species-specific and demand a consideration of specifically hominin evolution. That said, it is the same underlying middle-level theories that describe the selection mechanisms in all species.

A Short Introduction to Evolutionary Psychology

Evolutionary psychology is really indistinguishable from mainstream psychology if one considers research methods, statistics, or even to a large degree the journals evolutionary psychologists publish in. And despite what some critics argued, there probably are no differences in politics either (Tybur et al. 2007). More than traditional social psychologists, and despite changes in the last decade, evolutionary psychologists share a natural science epistemology and an acceptance of biological underpinnings to social cognition. That is not surprising given the fact that the most basic tenet of evolutionary psychology is that many relevant human psychological abilities, traits, or phenomena are the results of directional natural, social, or sexual selection.

One of Cosmides and Tooby's foundational contributions is the formulation of how the mind is best conceived within evolutionary psychology. While many other psychological theories either have no precise formulation of how the mind may be understood, evolutionary psychologists suggest that the mind is best understood as a mosaic of mental mechanisms. This is what is referred to as the modular mind. These modules are not fully informationally encapsulated; they are partially interconnected and communicate with each other, but particular parts are not

connected to all other parts, and they all process information differently. These modules are, as stated above, considered to be mental adaptations, results of selection. They are therefore behavior-generating mental organs evolved to solve specific tasks relevant to reproduction and survival. They are therefore also context dependent to some degree, with a certain expectation of specific forms of input. These mechanisms contributed to increasing fitness due to processing information according to certain rules and generating fitness-enhancing behavior in evolutionary relevant ecologies in our species' past. The sum of these mental adaptations and their output make up human universal nature.

Methodologically, as mentioned above, the aim is to apply knowledge about the past environment and evolutionary middle-level theories to generate original, testable hypotheses and predictions (Buss 1995; Tooby and Cosmides 1990b). These predictions are often concerned with specifying the functionally specified mental mechanisms, and specific predictions will suggest how these will process relevant information. This functional cognitive approach to hypothesis generation is at the heart of what makes evolutionary psychology stand out among psychological research programs. While most psychologists probably agree with evolutionary theory being the only explanation of how life has diversified and adapted to local ecological demands, psychologists in general seldom consider how evolutionary middle-level theories can help specify the information-processing mechanisms they study. Also, evolutionary theory is generally considered explanatory, not hypotheses generating. Further, while in the recent years most psychologists, even within social psychology, will accept a biological underpinning of mental activity, continued resistance to considering human behavior as a result of natural and sexual selection still exists.

A Meeting During an Earthquake

Ground shifting science rarely happens while the ground actually shakes. It did for evolutionary psychology. In the years 1989–1990 (during which the Loma Prieta earthquake occurred), David Buss collected five major names within

evolutionary psychology at the Center for Advanced Study in the Behavioral Sciences in Palo Alto for a special center project entitled “Foundations of Evolutionary Psychology.” Although no great manifest was published, there is little doubt that this was an important meeting given the theoretical and empirical output over the next few years from all involved. The five were, of course, Margo Wilson, Leda Cosmides, John Tooby, Martin Daly, and David Buss. These are therefore the founders whose work and contributions will be considered in further detail below.

Wilson and Daly: Young Male Syndrome and Homicide

Margo Wilson and Martin Daly are two of the most important pioneers of empirical research into human behavior from a psychological and evolutionary perspective. Science only grows and matures through data collection and hypothesis testing. While theoretical contributions are necessary to formulate a research program and develop the hypotheses to be tested, without empirical research, there will be little development.

Beyond their own scientific contributions, it is probably a safe claim that they influenced the field immensely with their editorship of the Human Behavior and Evolution Society flagship journal. This journal changed its name from *Ethology and Sociobiology* to *Evolution and Human Behavior*, marking both theoretical development and its increased scientific impact.

Young Male Syndrome

Sex differences are still a source of controversy within the social sciences and even to some degree within psychology. Many differences are quite small, and generally evolutionary psychology is not as interested in such differences: Relevant differences must have been due to stable evolutionary selection forces over evolutionary time and differences predicted by evolutionary middle-level theories.

Who will take the most risk? Based on sexual selection theory and analyses of age and sex, Wilson and Daly (1985) point out that those who have had the greatest reproductive competition

and are at greatest danger of not reproducing are young men. They consider how many violent crimes may be the result of status competition, however petty the situations that can lead to violence among men might seem (e.g., bar fights). These male-male violence and status competitions are driven ultimately by increased reproductive success among young men who can acquire status, as risk-taking behavior including crime and violence has historically been one possible avenue to greater status for disenfranchised young men. They report how specifically young males but not young females show a surge of violent crime after puberty. Without the *young male syndrome*, many crimes might not be committed. War might not even be possible without this effect. One needs a certain hypophobia concerning one's own mortality, as pointed out by Tooby and Cosmides in their analysis of the necessary psychological foundations of human warfare. The paper also considers general risky behavior among young men, including gambling.

Risky lifestyle choices, including risk-taking behavior, lead to increased mortality. Kruger and Nesse's studies on male to female mortality ratios have continued this line of work. Being born male is the greatest epidemiological risk factor for early mortality in Western countries. Research on risk versus worry highlights how both women in general might worry more, but men – especially young men – may be in danger due to being hypophobic, a concept used by Marks and Nesse to describe less than normal levels of anxious activation. The concept of the young male syndrome therefore sets the stage for a different appreciation of relevant health psychology and safety and risk phenomena based on an understanding of the function of reduced anxiety and greater risk-taking behavior in a specific subset of the population.

Homicide

Who kills who? And when and why do people kill each other? Daly and Wilson's (1988) classical book *Homicide* was groundbreaking as it was explicitly based on an evolutionary approach to behavior. Most importantly, and despite a background in comparative psychology, it focused on

specific human behavior, and it left mere theoretical speculation behind: It backed up several of the theoretical a priori predictions with evidence from official registers. This was novel. As such, it mapped an epidemiology of violence and abuse from an evolutionary psychology perspective, actually stating this explicitly and using the concept of evolutionary psychology in the foreword. From violent crimes to killing of kinfolk, Daly and Wilson chronicled different aspects of the history of homicide, human life history, evolved sex differences, and the killing of family members.

One of the most discussed and challenged results of this evolutionary approach to murder and abuse was the *Cinderella effect*, the increased likelihood of stepparents killing their partner's child, compared with biological parents killing their own children. This finding has been challenged both on the basis of findings from different countries and on the basis of bias in the registration of murder and abuse of children. In both cases, correcting the sample statistics suggests that there might be differential rates of murder across nations as well as a bias for registration of stepparents as perpetrators, but in general the Cinderella effect is supported and robust, and no other explanation has outcompeted the original evolutionary perspective. As a side note, even if one resorts to attachment theory for a competing explanation, it is surprising that critics are not aware that in their eagerness to refute one evolutionary perspective, they are actually invoking another. Finally, it is important to make clear how the Cinderella effect works: Many believe that Daly and Wilson are suggesting that humans, like lions taking over another male's pride, kill children that are not theirs to increase their own fitness. This is explicitly not what Daly and Wilson claim; they refute this position in *Homicide*. Their position is that for stepparents the bond that prevents parents in general from hurting their children is weaker, and therefore, some stop mechanisms have reduced function. They are therefore not arguing that biological parents cannot kill their offspring or that stepparents in general will hurt their stepchildren. At the population level, the Cinderella effect is still a statistically documented phenomenon.

Cosmides and Tooby: Human Universals and Interpersonal Competition

John Tooby and Leda Cosmides were recently awarded the lifetime achievement award by the HBES. They may be considered the most influential theoreticians within EP and probably the founders of the basic theory through their theoretical papers in the 1980s and early 1990s. While some of the theoretical claims such as the non-adaptiveness of personality differences might not be accepted by the entire field, their work on human universals sets the stage for a social-cognitive evolutionary psychology situated safely within normal psychological science methodology. At the same time, their attacks on the Standard Social Science Model (SSSM) created a certain distance to social psychology and social science, but highlighted the necessity of functional analysis, which they rightly claimed given their own fruitful methodology is not an explanatory luxury; it is a tool which when properly applied provides novel insights into how cognitive mechanisms function.

Culture, Learning, and Evolved Human Universals

In one of the most provocative and misunderstood essays, Tooby and Cosmides (1992) identify and criticize the Standard Social Science Model (SSST). They suggest that explanations of behavior that rely merely on invoking the general concepts of culture or learning as explanations in themselves – without actually explaining the mechanism of transference in detail – are not scientific. This criticism caused reactions, including a misplaced conclusion that evolutionary psychology is adverse to learning in general. The biophobic social scientist was also, according to detractors of Tooby and Cosmides position, a strawperson. Many researchers claimed that there was more attention given to the biological underpinnings of culture and learning than Tooby and Cosmides acknowledged. On the other hand, the lip service to such biological factors with no place for any specific theory, no methodology that accounted for the relevance of such factors, and a general reflexive dismissal of all attempts to add functional approaches to scientific explanation was

exactly what Tooby and Cosmides were targeting. Most evolutionary psychologists have met these alleged straw men among both editors and reviewers, as well as colleagues. Actually, to some degree, some evolutionary psychologists share SSST features in their thinking about development, with regard to behavioral genetic findings.

There was no dismissal of learning nor culture, as relevant and important phenomena in this essay. Only a very clear caveat that learning is not an explanation without further specification of what exactly it is that one means. It is very unlikely that Skinner would have disagreed with their critique of the simple incantation of general learning by general mechanisms without further evidence and description of the mechanism, including the possible evolutionary history of the learning mechanism. This essay largely functioned as a call to arms for evolutionary psychologists, laying the foundation for a more stringent science of both learning and culture from an evolutionary perspective. As such, one might note that it was considered more convincing in the long run by psychologists than by anthropologists.

Solving the Wason Selection Task

The Wason selection task is a logical problem in which people are shown four cards. They have a numeral printed on one side and a letter on the other side. They are placed on the table in front of the participant. Two of these cards are dealt with the numeral facing up; the other two show the letters, for example, [7][H][3][D]. The participant is then given a rule for the cards and asked which card(s) to turn to test the rule. In this case the rule is behind every [D], there is a [7]. The question then is: Which cards would you turn? Typically, people are governed by their confirmation bias. They therefore flip over [7] and [D], in both cases to confirm the rule rather than attempting to falsify it. This phenomenon occurs irrespective of intelligence and education. Furthermore, when people have learnt the solution of by heart, they will in some cases still provide erroneous explanations, yet again reverting to their confirmation bias – which illustrates how strong this tendency is. The correct answer, which is not typically the human response,

is to flip over [3] to find a [D], and the most difficult, to flip over [D] to *not find a* [7].

It may seem strange, given how much more attention sexual research gets, that an abstract cognitive bias test was probably the single empirical research finding that paved most of the way for EP as a specific scientific research program. While Tooby and Cosmides have continued their research into coalitional, innate, and evolved psychology (including topics from war to incest avoidance), it all started with a groundbreaking finding: that human limitations in solving logical problems, documented in a multitude of studies, vanished once they were made ecologically relevant for detecting social contract rule breaking (Cosmides 1989).

It is not particularly important what social contract rule one tests; it can be made up or a familiar social rule in participants' culture. If the rule to be tested is a social contract rule and there are potential cheaters to be detected, people solve the Wason selection task much more frequently. Note that from a logical perspective, the problem and solution are the same.

Consider this example: Four cards representing four people in a seedy bar. The rule is that only those who are older than 18 may drink beer. The cards display the age (either above or below 18) on one side and what the person is drinking (either soda or beer) on the other. The four cards show [Soda] [Beer] [Above 18] [Below 18]. Who do you want to check, to test the rule? While most people want to check and confirm [D] and [7] above, that solution is no longer interesting. Now most people want to find cheaters. Most people want to see whether the person below 18 is drinking beer (falsification not confirmation) and how old the beer drinker is (yet again and contrary to what one does in the non-social cheating context, in order to check whether the person is too young).

In other words, we become natural Popperian falsifiers and ditch our normal human confirmation bias problems if someone might be breaking a social contract. This applies to the majority of people, and it is not dependent upon familiarity or cultural context. Finally and most importantly, it was not predicted by any other theory. Perhaps

most surprisingly, there is probably dedicated neural circuitry involved in cheater detection (Stone et al. 2002) – which in turn provided support for the modular approach.

Why should we be good at discovering cheaters? We are hyper-social intelligent animals, both dependent upon and in active competition with other humans. We are able to make social rules and break these same rules. Being naïve about rule breakers is not a viable evolutionary strategy. The finding that a module for solving a specific, adaptively relevant problem could make us better at solving generally unsolvable logical problems was groundbreaking. The immense creativity of these founders, and their ability to succinctly formulate the basic theoretical logic underlying many psychological problems, has resulted not only in fundamental theoretical papers: research into other social, coalitional cognitive processes, such as welfare-benefit ratios and race perception followed from the same interest in the underlying evolved adaptations and provided our science with findings and explanatory principles that were both original and counterintuitive.

Strategic Modeling

Together with Irvin DeVore, John Tooby wrote a classic on why human evolutionary psychology must take into account specific human evolution. While many earlier approaches to human evolutionary behavioral science were to a large degree comparative, Tooby and DeVore (1987) point out that in order to study the species-specific adaptations of humans, such an approach will be severely limited. Evolutionary psychology is therefore to a much lesser degree comparative in its general approach than sociobiology was or to the degree that more biological approaches to human psychology often are. While homologous structures exist, when considering human nature, it is primarily relevant and even imperative to consider specific hominin evolution and selection, especially those traits that are unique to humans. This gem is not as often cited as it ought to be but provides insights into how early evolutionary psychology theorizing differed from other evolutionary approaches to both animal and human

behavior. While many academics believe that humans are freed from the animal shackles of evolution, Tooby and DeVore suggest that the complexities of proximate mechanisms hide the fact that the ultimate function has not changed. Strategic modeling of complex proximate mechanisms is therefore a tool to reduce such complexity, which reveals how they are “adaptively patterned.” Note that while this chapter is primarily a contribution to paleontological modeling of hominin species, the principle strategic modeling they suggest is most relevant as a metatheory of evolutionary and behavioral analyses of function and specific human evolution.

Buss: Individual Differences and Mate Preferences

Mate choice is a fundamental aspect of evolution, and mates vary. There are individual differences among potential mates, and we choose among these potential sexual partners either to mate romantically for life or for the sexual thrill of the moment. If someone were to steal our romantic partner, it would hurt us, both emotionally and through possible fitness costs. All of these areas that might seem very familiar to anyone with an interest in evolutionary psychology have been pioneered by David Buss. And beyond important theories such as sexual strategy theory, with David Schmitt, and error management theory with Martie Haselton maybe Buss is the researcher that has provided the field with the broadest and deepest empirical basis. This has also aided the communication of evolutionary psychology to the rest of academic psychology. For the field, his textbook and *The Handbook of Evolutionary Psychology* have become landmarks, improving the teaching and uniting the field.

Cross-Cultural Mate Preferences

Cross-cultural research has not been typical in social sciences in general or psychology specifically. While critics of merely considering Western, Educated, Industrialized, Rich, and Democratic (WEIRD) populations have made important corrections to the generalizability of psychological research, it is worth noting that from early on evolutionary psychology has been

oriented toward cross-cultural studies and more so than many other areas of psychological research. One of the most groundbreaking of these evolutionary cross-cultural studies was David Buss’ mammoth collaborative study of mate choice in 37 cultures.

Building on his early work on mate choice (Buss 1985), and inspired by Don Symons’ (1979) work on human sexuality and human universals, Buss started collecting one of the largest international data sets at the time. While some have criticized the cultural variance and national sample sizes, this is a landmark study, with few studies in psychology, and especially cross-cultural studies, coming close in influence and citations.

Buss (1989) reported several cross-culturally robust similarities between the sexes. For example, both men and women are interested in intelligence and agreeableness traits, especially in long-term relationships. On the other hand, stable male-older findings, where both sexes seem to agree that he should be older than her, greater male interest in female physical attractiveness, and greater female interest in male financial prospects suggested evolutionarily predictable sex differences in partner preferences. These original findings have been reproduced repeatedly and have proven to be stable across cultures as well as within cultures across time. Age preferences have also received attention in the last few years. While many critics of evolutionary psychology have attempted to challenge these findings on human universal mate preferences, they appear to be among social psychology’s most replicated conclusions.

Evolutionary Personality Psychology

There are two major approaches to the science of psychology reflected in many areas of research. In some disciplines and theories, one considers human universal nature, and the theories and findings are considered relevant for all humans. Such areas include learning psychology and to a large degree social psychology in general. Personality psychology, on the other hand, considers individual differences. This is one of the interesting areas of open disagreement among the founders of

EP. The basic formulation of EP by Tooby and Cosmides (1990a) focuses explicitly on human universals and does not even consider sex differences in their study of evolved mental mechanisms. As mentioned above, EP is in its original formulation by Tooby and Cosmides, largely a theory of the minds of both men and women, equally. Tooby and Cosmides (1990a) were quite explicit about personality and other individual differences not being key areas of study from an EP or adaptationist perspective. There is therefore a certain shift in focus in different directions even within mainstream EP. On the other hand, they suggested mechanisms that could explain adaptive individual differences, including frequency-dependent selection and their concept of reactive heritability (where, e.g., some traits are more efficient in specific bodies or in concert with other traits and thus may become more expressed under the right and adaptive circumstances).

A full understanding of human nature demands that we also understand the evolution of stable differences in fitness-relevant behaviors, as defined by traits. Also, trait psychologists have suggested that evolutionary psychology has to address the question of how the five major personality traits of openness, conscientiousness, extroversion, agreeableness, and neuroticism have evolved (Nettle 2011). David Buss pioneered the area of evolutionary personality psychology, which has been slow to gain momentum in empirical data collection, but in recent years' has increased with interest in life history approaches. Future empirical testing is still much needed for evolutionary personality psychology data collection to catch up with theory generation. At the moment, we have different approaches within EP that consider either how individual differences in life histories may provide testable predictions about behavior, but also theories of how the five major personality traits are a result of specific evolutionary processes, including selective neutrality, frequency-dependent selection, and mutation-selection balance. We need more work testing different hypotheses. At the same time, from an evolutionary personality psychology perspective, it would be odd if these value-laden descriptions of others that make up

the basis of traits had not been relevant for selection. Noise or adaptive? We still do not know. This area still needs more evidence.

Sexual Strategy Theory

Formulated with David Schmitt, sexual strategy theory (SST) is one of the most influential approaches to the understanding of human sexual behavior (Buss and Schmitt 1993). SST starts with the general principles of Trivers' (1972) parental investment theory, but specifies the theory for human women and men and our species-typical adaptive sexual problems. An important contribution of the theory is the attention given to mating context as well as sex: Men and women have different preferences and behavior in short-term and long-term mating contexts. This lays the foundation for several predictions about how men and women in short-term and long-term mating situations will act or display preferences.

Women and men have engaged in both long-term and short-term sexual relations throughout evolutionary history and been selected for these kinds of behavior if the benefits outweigh the average cost. But each context presents different adaptive problems for the two sexes. Due to differences in minimal parental investment and possibilities to benefit from multiple matings, men will have greater interest in short-term sex than will women. This exemplifies one adaptive problem difference, but there will be predictable similarities and differences between men and women in all four combinations of sex and context. Buss and Schmitt (1993) list the following four adaptive problems for men for either a long-term relationship or short-term sexual encounters:

Long-term relationships: (1) discerning reproductive value, (2) ensuring paternal certainty, (3) identifying good mothers, and (4) identifying willingness to commit

Short-term sexual encounters: (1) acquiring a large number of partners, (2) discerning who is sexually accessible, (3) discerning fertility, and (4) minimizing any investment and commitment

Note that reproductive value is very important for long-term relationships, while current fertility is relevant for short-term relationships. Similarly, minimizing investment is not as relevant for a monogamous long-term relationship. The ability and willingness to commit in long-term relationships will not differ between the sexes and should rank high among partner preferences for both sexes.

Women's reproductive success has not been constrained by access to sex, but rather access to resources and maybe genes of the men that are interested in investing in them and their offspring, both here and now and on a long-term basis. The following five adaptive problems need to be solved by women in the adaptive problem of acquiring the best possible long-term relationship (Buss and Schmitt 1993): discerning men who are (1) able and (2) willing to invest resources in her and her children on a long-term basis, (3) identifying men who will be good fathers, (4) identifying men who are willing and able to commit, and (5) identifying men who will be both able (formidable) and willing (aggressive) to defend them against other men.

The evolutionary perspective suggested that men and women have been selected so that they on average will solve the adaptive problems effectively when engaging in short-term sex or long-term relationships. While the word strategy might be confusing, the strategy is the evolved, effective solution to the adaptive problems, the mental adaptations solving context specific adaptive problems, with no conscious goal being assumed. Beyond being a very influential theoretical paper, it also provided data that tested direct predictions about, for example, male interest in both long-term and short-term relationships and interest in sexual variety.

SST met with criticism from mainstream social psychology. One claim was that our sexual psychology is inherently monomorphic, but cultural structures will cause differentiation. Therefore, detractors of SST believed one would not find similar results as in the American sample in other more gender egalitarian nations. Such criticism must be testable in order to be scientific; one cannot make such claims and not accept findings

from the world's most gender egalitarian nations as not relevant. Since 1993, hypotheses from SST have been tested internationally; in some cases, there are differences – with both smaller and larger sex differences being reported from more gender egalitarian nations than the USA. In general, though, these results have supported SST as the best theory for generating hypotheses about modern human sexual behavior and sex and context differences in preferences. For example, direct tests suggest that one finds almost exactly the same results for the original SST findings in a more gender egalitarian Norwegian sample.

Jealousy

It is simple: Imagine that there is no parental investment, no long-term relationships, and full knowledge of who both parents are. In this scenario there is no jealousy. Now, change a few things: Add father investment with no or low paternal certainty. Is it then possible that male sexual jealousy would not evolve? Men are among 5 % of mammals in which fathers invest in assumed offspring. Concealed conception results in less than complete paternity certainty, despite different cultural inventions that attempt to control female sexuality. What would happen to the more protective and skeptical or jealous men compared to the men who are naïve and uncaring about their partner's sexual escapades? The same is the case for women: What would happen to women who were uninterested in their partner's interest in investing in their joint children? Rather than attempt to prove how sex differences in jealousy evolved, one might turn that around: How could these specific types of interest in fatherhood or future resource investment *not* evolve? And what feedback mechanism could help us learn the effects? Men would never get to know the negative effect. If women did see the effect, it would certainly be too late.

Prior to Buss' original work on jealousy, psychologists were not aware of sex differences in jealousy: men being more distressed by sexual infidelity than emotional infidelity than women are (Buss et al. 1992). It is worth noting that it is the interaction that is relevant by testing whether men, relative to women, find sexual infidelity

more distressing than emotional infidelity. While the logic of the evolutionary theory seems convincing, there have been several challenges to the theory. First, that one sort of infidelity (either emotional or sexual) would elicit the conclusion that the other form had occurred, so that there was not really a sex difference. This was called the double-shot theory. It is simple to test: One changes the question from “what is most distressing, sexual or emotional infidelity?” to “if both sexual and emotional infidelity have occurred, which type is most distressing?” In this double-shot scenario, sex differences persist. Another challenge is that the stable sex difference is not detectable with continuous measures, maybe due to ceiling effects. At the same time, continuous measures are considered more meaningful by some critics, and some suggest the sex difference is merely a methodological artifact. Recent work found that when randomly distributing either continuous or forced choice questionnaires in the same population, there was no difference between the two methodologies (Bendixen et al. 2015). This study also found that, rather than there being smaller sex differences in jealousy in more gender egalitarian nations, the effect sizes are larger, probably driven by greater expected male investment as proposed by Buss et al. (1992). Another criticism is that sex differences in jealousy might only hold for young, heterosexual participants. However, finding that postmenopausal female partners elicit less jealousy is congruent with evolutionary theory.

Considering Future Developments

Evolutionary psychology has developed during the almost 35 years since the first formulations of the evolutionary psychology basic theory, not just in general acceptance among academics and inclusion in mainstream psychology textbooks but also as a theory. In the beginning, the focus was largely on human universals, but there has been a clear shift toward considering individual differences in both normal personality (Buss and Penke 2015) as well as psychopathology (Del Giudice 2014; Kennair 2011) and the effects of cultural differences, highlighted by the work of David Schmitt. In the last few years, greater

emphasis has been placed on life history theory (Del Giudice et al. 2015), primarily as an explanation of individual differences, but also psychopathology. Furthermore, there is a continued interest in evolutionary developmental science. All of these areas need empirical and theoretical developments to be tempered with knowledge from the field of behavioral genetics in order to fully come to fruition. While many researchers are now considering how unstable childhood environments predict instability in personality traits or behavior of young adults, it is worth noting that behavioral genetics research suggests that parent-offspring similarities in general are due more to genetics rather than environmental influences.

The many students of the founders have also started making large contributions in their own right, both empirically and theoretically, and many of these may be considered part of the foundations of EP. Two select examples: Martie Haselton and David Buss's (2000) *error management theory*, is generating both supportive and critical research within EP. Also, research on race perception, originally developed by Kurzban et al. (2001), is providing an evolutionary base for conceiving of race as merely one of many arbitrary and therefore inherently malleable out-group cues.

Conclusions

These five founders of EP as a specific research program have established an evolutionary-based approach to psychological research, which over the last three decades has become part of mainstream psychological science after initially being considered both politically and scientifically suspect. At the same time, there have obviously been many other influential figures in the field who have inspired the development of both evolutionary psychology research and theory, both by challenging and developing the original formulations. As such, the area of study has been influenced by critics, students, and colleagues working around the globe in collaboration and competition.

Four-Stage Model of the Sexual Response

Lora E. Adair

Lyon College, Batesville, AR, USA

Synonyms

[Human sexual response](#); [Sexual response pattern](#); [The sexual response cycle](#)

Definition

The four-stage model of the sexual response is a descriptive model of the physiological changes which correspond with human sexual arousal and sexual behavior. In the four-stage model of the sexual response, the typical markers of arousal are organized into a temporal framework. This model was proposed by Dr. William Masters and Virginia Johnson (1966) and made possible by their groundbreaking research, including the systematic physiological recordings of individuals and couples engaging in sexual contact in the laboratory. The four stages of the human sexual response cycle, as defined by Masters and Johnson (1966), are (1) excitement, (2) plateau, (3) orgasm, and (4) resolution.

Introduction

This entry will detail the four-stage model of the sexual response and will explain the physiological changes associated with human sexual arousal, particularly emphasizing the 1966 work of Masters and Johnson, *Human Sexual Response*. While

other works had – prior to the publication of *Human Sexual Response* – explicated physiological markers of the human sexual response (see Ellis (1928) *Studies in the Psychology of Sex* which particularly emphasized the destigmatization of sex and the need for sexual physiology and function to be taught in schools), Masters and Johnson uniquely relied upon physiological data and novel empirical methods to construct their four stage descriptive model of the sexual response cycle. This four-stage model of the sexual response *still* characterizes the understanding of the physiological substrates of human sexual arousal and behavior in the many domains of psychology (e.g., biological, social, evolutionary) which apply their own theoretical perspectives and methodologies to the study of human sexuality.

Four-Stage Model of the Sexual Response

The four-stage model of the sexual response was (1) based upon direct observations and recordings of human sexual activity (partnered and solitary) in the laboratory and (2) used a body of existing scientific knowledge to construct a framework that would provide order to the tremendous individual differences in sexual responses and broad array of physiological changes that correspond with the experience of sexual and physiological arousal. According to Gray and Garcia (2013):

(Masters and Johnson's) model was built on cutting edge physiological studies of individuals and couples in a laboratory setting. They recorded responses as varied as male heart rate and female uterine contractions. Through these measures, they were able to document the most intimate physiological details in unprecedented, real-time, ways. For its time, their work was controversial. (p. 200)

This discussion will be organized into the (chronologically sequenced) stages of the human sexual response proposed by this model: (1) excitement, (2) plateau, (3) orgasm, and (4) resolution.

(1) Excitement

The four-stage model of the sexual response begins with the (1) excitement phase. This phase

is generally characterized by the initiation of physiological arousal. During the first phase, Masters and Johnson (1966) describe a response in the presence of “any source of somatogenic or psychogenic stimulation” (p. 5) wherein physiological arousal begins to build. While this stage does characterize the beginning of the sexual response cycle for solitary sexual practices (i.e., masturbation), colloquially the excitement phase is referred to as “foreplay.” During this initial stage, somatogenic or psychogenic stimulation produces an increase in heart rate, respiratory rate, blood pressure, and a dilation of the pupils – all general markers of physiological arousal (Pinel 2014). Also, the skin of the male and the female – particularly the chest, breasts, and back – becomes slightly reddened or “flushed,” called the “sex flush” by Masters and Johnson (1966). This reddening is particularly likely to occur in females, where the skin of the chest will become red and resemble a rash. Additionally, the female excitement phase is characterized by the labia majora thinning, parting, and beginning to “flatten against the perineum” (Masters and Johnson 1966, p. 38); the labia minora begins to lubricate the vulva and enlarge (Gray and Garcia 2013).

In males, a similar swelling of the external genitalia occurs during the excitement phase – the dilation of arteries (i.e., internal pudendal arteries) promotes the movement of the blood to the penis and scrotum, causing the penis to become erect and the testes to swell and lift closer to the pelvic floor (Masters and Johnson 1966). During the excitement phase, in females – and more variably in males – the nipples become erect. Masters and Johnson (1966) go on to characterize the excitement phase in males and females as being characterized by (a) increasing sensitivity to sexual stimulation (especially in areas such as the nipples, external genitalia, and anus), (b) increasing muscle tension, and (c) long duration (compared to the rest of the phases of the sexual response cycle). In fact, many therapists recommend long durations of foreplay to promote the achievement of sufficient arousal and stimulation to reach orgasm, particularly for females (Gray and Garcia 2013).

(2) Plateau

According to Masters and Johnson (1966), a transition to the second phase of the response cycle is characterized by an increase in intensity of physiological arousal (due to continued stimulation) during the excitement phase. The second phase, the plateau phase, is described via this increased intensity of arousal and characterizes the physiological changes that facilitate the transition between initial arousal/excitement and the experience of orgasm. For females, the physiological changes which characterize this second phase of the sexual response cycle are a continuation of the lubrication (facilitated by the activity of Bartholin's glands) and swelling of the labia minora; according to Masters and Johnson (1966), "... the labia minora increase at least two, occasionally three, times in diameter" (p. 41). Further, "vivid color changes develop in the engorged minor labia during the plateau phase of the sexual response cycle" (p. 41), termed "sex skin" by Masters and Johnson. Interestingly, the reddening of skin has – in the evolutionary history of primates – served as a signal to nearby potential mates. A reddening and swelling of the vulva is common in many species of (female) primates and is hypothesized to function as a signal of sexual receptivity (i.e., peak fertility) rather than a mere correlate of the experience of sexual arousal (Dixon 2012). Females also experience the continuation of the parting, thinning, and elevation of the labia majora during this phase. Additionally, the clitoris typically retracts during the plateau phase – but is hypothesized to do so in response to physical stimulation, rather than as an involuntary physiological precursor to orgasm (Masters and Johnson 1966). The vaginal walls continue to display signs of vasocongestion, and the vagina increases (only *very* slightly) in width and depth.

Males also continue to experience vasocongestion of the external genitalia – the scrotum continues to enlarge, the testes continue to elevate, while penis size changes very little during the plateau phase as full erection is typically achieved during the excitement phase (Masters and Johnson 1966). While the male

experience is much more variable (e.g., this can occur during some sexual encounters and not others and is not observed in the majority of men), males may also experience a reddening of the external genitalia, namely, the glans of the penis. Males may also experience increased sensitivity to physical stimulation during this phase and pre-ejaculatory secretions (Gray and Garcia 2013). In a general sense, the physiological changes which characterize the plateau phase are a continuation and intensification of physiological changes which have been initiated during the excitement phase, for both the male and the female.

(3) Orgasm

Continued "adequate" (Masters and Johnson 1966, p. 6) stimulation during the plateau is required for the individual to achieve the third phase, orgasm. In fact, Masters and Johnson (1966) indicate that certain specific physiological changes during the plateau phase (e.g., the reddening of the labia minora) *always* cue the imminent experience of orgasm. In other words, experience of sufficient continued somatogenic and/or psychogenic stimulation to produce many of the physiological changes that characterize the plateau phase would *inevitably* produce orgasm. While the excitement and resolution phases of Masters and Johnson's four-stage model of the sexual response are the longest in duration, orgasm is the shortest.

The female experience of orgasm is characterized an experience of peak intensity of many of the physiological markers of the excitement and plateau phases, such as the "sex flush" of the skin, hyperventilation, and increased heart rate. Involuntary muscular spasms of the muscles in the neck, arms, abdomen, buttocks, legs, and face are experienced during orgasm. Vaginal and uterine contractions also occur (the uterus lifts away from the pelvic floor), wherein greater frequency and intensity of these contractions are associated with a stronger subjective experience of orgasm – over time these contractions rapidly decrease in frequency and intensity. Importantly, Masters and Johnson (1966) performed empirical work regarding the physiological correlates of female orgasm

which contradicted a popular perspective regarding the function of orgasm at the time – the “upsuck theory.” According to this perspective, “during orgasm the uterus develops some form of pressure and sucks the seminal fluid through the external cervical os into the cervical canal” (p. 122). Masters and Johnson used a “reasonable facsimile of seminal fluid” with a radioactive tracer to determine the extent to which uterine contractions associated with orgasm facilitated the movement of seminal fluid into the endometrial cavity. Masters and Johnson concluded that “in none of the six individuals was there evidence of the slightest sucking effect on the media in the artificial seminal pool” (p. 123).

The male experience of orgasm is similarly described as an experience of peak intensity of many of the physiological markers of the excitement and plateau phases, such as the “sex flush” of the skin, hyperventilation, and increased heart rate – as well as the occurrence of “total body” muscular spasms. Characteristic of the male experience of orgasm, and unique to the male experience of orgasm, is the expulsion of seminal fluid through the urethral meatus (Masters and Johnson 1966). Furthermore, males experience rapid contractions of muscles in the pelvic floor and surrounding the external genitalia (e.g., the deep perineal, sphincter urethrae, and the transverse superficial perineal muscles).

Consistent with evolutionary explanations of the experience and function of female orgasm, which suggest that the complexity and variability of females’ orgasmic experience serve as an opportunity to evaluate the commitment and investment of their sexual partner (Puts et al. 2012), Masters and Johnson (1966) explain: “There is great variation in both the intensity and the duration of female orgasmic experience, while the male tends to follow standard patterns of ejaculatory reaction with less individual variation” (p. 6).

(4) Resolution

The final phase of the sexual response cycle, resolution, is generally characterized as a disappearance of the physiological markers of excitement

and orgasm. That is, the slowing of respiration, constricting of the pupils, lowering of blood pressure, and slowing of heart rate. For females, the “sex flush” and reddening of the areolae and labia minora quickly disappear, while the swelling of the breasts (due to vasocongestion) decreases much more slowly. The clitoris returns to its homeostatic, unretracted state as the shaft of the clitoris relaxes (notably, quite similar to the relaxation of the shaft of the penis following ejaculation (Masters and Johnson 1966). The vagina decreases in diameter, the uterus lowers toward the pelvic floor, and lubrication of the labia minora and vaginal walls ceases. Interestingly, Masters and Johnson (1966) note that continued lubrication and vasoconstriction observed in the vulva during the resolution phase provide a cue to a female’s propensity to quickly return to the orgasmic phase.

In males, the experience of resolution is typically characterized by a rapid loss of penile erection; however, erection may be maintained after the experience of orgasm of physical stimulation of the penis persists (Masters and Johnson 1966). During this phase the “sex flush” on the chest, neck, and back and reddening of the glans of the penis disappear, the scrotum lowers, testicular size decreases, and the testes descend lower into the (now relaxed) scrotum. Masters and Johnson also describe the significant variability in males’ ability to achieve multiple orgasms in a short period of time – while some of their participants were able to achieve as many as three orgasms in 10 min, the time needed between the experience of the resolution phase and the reinstatement of physiological markers of excitement depended greatly on age. Older males typically required longer durations of time to pass between the experience of resolution and the reinstatement of excitement and plateau (Masters and Johnson 1966).

Conclusion

Masters and Johnson’s (1966) the four-stage model of the sexual response was, importantly,

based upon direct observations and recordings of human sexual activity in the laboratory and thus provided clinicians and researchers with a deeper understanding of both the physiological and the psychological correlates of the human sexual response cycle. Their work revolutionized the treatment of sexual dysfunction and disorder, increased understanding of sexual activity in aged populations and the female capacity to experience multiple (rapid) orgasms (both topics surrounded by much stigma and misunderstanding), and constructed a framework that would provide order to the broad array of physiological changes that correspond with the experience of sexual and physiological arousal.

Francis T. McAndrew

Paul B. Harris

Rollins College, Winter Park, FL, USA

Definition

Teacher, scholar, and essayist in evolutionary psychology.

Introduction

Francis “Frank” T. McAndrew is the Cornelia H. Dudley Professor of Psychology at Knox College, a small private liberal arts college located in Galesburg, Illinois. In academic circles, McAndrew is probably best known for his popular 1990s textbook *Environmental Psychology* (McAndrew 1993) and for his more recent research exploring the psychology of gossip (McAndrew et al. 2007; McAndrew 2014, 2016, 2017). In the public arena, he may be best known for his numerous print, radio, and television interviews discussing the evolution of social behavior and for his *Psychology Today Magazine* blog “Out of the Ooze: Navigating the 21st Century with a Stone-Age Mind” (www.psychologytoday.com/blog/out-the-ooze).

McAndrew was born in Augsburg, Germany, in 1953 where his father was stationed with the US Army; the family moved back to The USA before his first birthday. Along with two brothers and two sisters, young Frank would spend his childhood in Northeastern Pennsylvania; the first 6 years in Scranton and the remainder in the small borough of Dallas. McAndrew writes, “from kindergarten through college I survived 17 years of Catholic education, and my only noteworthy achievement during my school days was being a two-time place winner in my high school state wrestling tournament. Except for that, I mostly just hung around a lot” (<http://faculty.knox.edu/fmcandre/biography.html>). Wrestling turned out to be a lifelong love of Frank’s – he was a member of the wrestling

Foxes

- [Canines](#)

team during his undergraduate years at Kings College in Wilkes-Barre, Pennsylvania, and was a member of the wrestling coaching staff at Knox College for 27 years, including 12 seasons as Head Coach.

During his senior year at Kings College, McAndrew found another lifelong love in sophomore Maryjo McCarthy. Although he graduated in 1974 and moved to Orono to pursue his doctorate at the University of Maine, the bond between Frank and Maryjo continued to grow and they were married in 1978. They have now been married for nearly 40 years, have two grown children and a granddaughter.

In 1981, McAndrew received his Ph.D. in General-Experimental Psychology from the University of Maine. His research at the time related to social aspects of nonverbal behavior and human territoriality. It is unlikely that he would have classified himself as an evolutionary psychologist at the time, but during the 1970s both areas of study were heavily influenced by research in ethology and comparative psychology. McAndrew, who also did graduate work in zoology at Maine, was undoubtedly drawn to the connections between biology and psychology.

In 1979, a year after his marriage and 2 years before defending his dissertation, McAndrew took a job as an instructor of psychology at Knox College. This job would transition to assistant, associate, full, and ultimately endowed professor positions. Working as faculty at a small liberal arts college has undoubtedly had a profound impact on McAndrew's teaching and scholarship. At the time he started at Knox, and many years after that, he was one of three faculty members in the Department of Psychology (current staffing is at seven). Such a small teaching staff requires faculty to be generalists rather than specialists. During his time at Knox, McAndrew developed 17 different courses on diverse topics including animal, cognitive, environmental, evolutionary, history and systems, industrial/organizational, introductory, quantitative, and social psychology. In addition to these classes, and on top of the variety of committee work expected of faculty,

McAndrew was also instrumental in founding Knox's Environmental Studies Program, directed this program for 7 years, and chaired his department for 9 years. This breadth of courses and responsibilities did not diminish the quality of McAndrew's teaching; among the honors he has earned are the college's top award for distinguished teaching both in 1983 and 2000; top award for faculty achievement in 1999, 2009, and 2013; and the Cornelia H. Dudley Endowed Chair in Psychology (1998 to present).

McAndrew's program of research has also been influenced by his position at Knox College. In line with the school's emphasis on undergraduate education and experiential learning, every psychology major is expected to design and carry out a two-term research project (three-term for honors students). From a faculty perspective, this means that scholarship typically involves collaboration with undergraduate researchers and each project requires a new set of negotiations to find topics of mutual interest between students and mentor. The outcome of this process is often a larger number of smaller publications (i.e., that can be completed in an academic year) that are thematically eclectic (i.e., reflecting diverse student interests). A review of McAndrew's vita reveals studies in environmental psychology, nonverbal behavior, gender and stereotyping, adoption and namesaking children, aggression, altruism, and more recently on gossip and attributions of "creepiness." Almost two to two thirds of McAndrew's peer-reviewed journal articles have undergraduate coauthors, many of whom have gone on to graduate school.

Despite the diversity of topics in McAndrew's publications, there is also conceptual continuity in his program of research; McAndrew writes, "To the extent that there is a common theme tying my research together, it is that I study human social behavior from an evolutionary perspective" (<https://www.knox.edu/academics/majors-and-minors/psychology/faculty/mcandrew-frank>). One of these recurring themes over the past two decades has been the evolutionary psychology of gossip. At the time of this writing, McAndrew has nine academic and five

popular press publications on this topic, as well as a book in the works, several conference presentations, and over 20 invited talks. The idea that gossip might serve an adaptive function in the species has also caught the public's attention, as evidenced by numerous interviews with McAndrew, and references to his research, in documentary film and popular television, radio, Web, and print media (well over 100 to date).

Perhaps because of the popular interest in his research on gossip, McAndrew has recently branched out as an essayist and blogger, sharing his passion for evolutionary psychology with the public at large. In his *Psychology Today Magazine* blog "Out of the Ooze: Navigating the 21st Century with a Stone-Age Mind," McAndrew has presented an evolutionary perspective on such topics as masculinity and gun violence, social media and identity, "creepiness" in people and places, the fleeting nature of positive emotions, religious experience, and, of course, gossip. In all his posts, McAndrew's knowledge of the field, remarkable talent as an educator, and wry sense of humor shine through.

Conclusion

For nearly 40 years, Frank McAndrew has been studying, promoting, and contributing to the field of evolutionary psychology in the classroom, through his research, and through his popular publications. No doubt his ongoing efforts to "study human social behavior from an evolutionary perspective" will continue to intrigue and inform his students, the discipline, and the public at large.

Frank Sulloway (1996) On Birth Order

Catherine Salmon

University of Redlands, Redlands, CA, USA

Synonyms

[Family order](#); [Ordinal position](#); [Sibling position](#)

Definition

The sequence in which children are born into the family.

Introduction

In 1996, Frank Sulloway's book *Born to Rebel: Birth Order, Family Dynamics, and Creative Lives* was published. In it, he outlined his adaptationist approach to birth order focusing on differential parental investment and sibling competition. The book documents personality differences by birth order and how they play out in terms of revolutions in science, religion, and politics. It has also spawned a new generation of research into birth order effects, not just

concentrating on effects on personality but also examining the impact of birth order on behavior.

Role of Parental Investment in Creating Birth Order Effects

Parental investment is any investment that a parent makes that increases the likelihood of an offspring's survival and reproduction at the cost of that parent's ability to invest in other current or future offspring (Trivers 1972). This can be anything from providing food and shelter to attention, education, and other financial support. As Sulloway articulated, the importance of birth order to parental investment is related to both the age of offspring and age of the mother. An offspring's expected contribution to parental fitness rests mainly in their reproductive value which increases with age until puberty, making older immature offspring more valuable from a parental fitness perspective than younger ones, as discussed in full in Daly and Wilson's work (1988) on the psychology of discriminative parental solicitude. It is this assurance of parental favoritism (and the lack of early competitors) that makes firstborn children defenders of parental values and the status quo while laterborns are more frequently rebellious. However, lastborns may also get some special benefit from being the last one born, the last opportunity to invest, and from being born to older mothers, all else being equal. Which likely accounts for the curvilinear birth order effects that are sometimes found with regard to aspects of parental investment such as money provided by parents for college (Kennedy 1989; Salmon and Schumann 2011). It is also possible that even when parents intend to allocate resources equally among their children, the cumulative result is inequity due to parental resource variability over the lifespan (Hertwig et al. 2002).

Sibling Niche Theory

Sulloway has suggested that children adopt different roles or niches within the family due to sibling competition over limited parental resources.

Specialization of roles within the family, like specialization of species in the wild (such as Darwin's finches), reduces levels of sibling competition. Specialization also makes children more unique. Eldest siblings often occupy the role of surrogate parent with its responsibilities and adherence to rules. For laterborn children, there is no advantage to trying to duplicate the same role, they need to find their own niche and their openness to experience with less adherence to rules and authority facilitates this. Healey and Ellis (2007) provide supportive evidence for Sulloway's niche theory with regard to differences between firstborns and secondborns. This tendency for siblings to diversify makes adjacent siblings more different than those farther apart in age and with other siblings in between. It has also been suggested that while parental influence may tend to create linear birth order effects, sibling competition and diversification in search of a family niche will tend to create quadratic effects. Pollet and Nettle's (2007) study of face to face contact with siblings reports that firstborns are more likely to take on the role of family contact, taking on the responsibility of keeping track of and informing siblings of family news. An excellent study by Paulhus, Trapnell, and Chen (1999) also tested Sulloway's Darwinian model of birth order effects on personality using the preferred method of within-family data and having respondents compare themselves and their siblings on a number of personality dimensions with results supportive of the achieving/conscientious firstborn and the rebellious/liberal/agreeable laterborns. In a similar vein, Sulloway and Zweigenhaft (2010) tested the risk-taking lastborn niche by examining participation in risky athletics and major league baseball in particular, reporting on 700 major league brothers, demonstrating that laterborn brothers engage in risky strategies (such as base stealing) more frequently and more successfully than firstborns.

Functional Birth Order and Adaptive Strategies

Sulloway also emphasized the importance of attending to what he referred to as functional birth order. There is a difference between

biological order of birth and functional birth order which focuses on the environment one is born into with particular attention on the family niche one ends up in. Typically, biological and functional birth order may be the same. However, there are factors that can shift the functional birth order of a specific sibling. For example, if the eldest sibling dies at a relatively young age, the next born child may end up taking on the firstborn role in the family. Other factors that can cause shifts in the functional birth order of siblings include disability, significant age gaps, adoption, and remarriage. This highlights the environmental nature of birth order as a variable influencing various traits and behaviors.

In addition, Sulloway drew attention to the adaptive strategy perspective on personality. Birth order differences in personality reflect the different strategies siblings adopt in their attempts to acquire the resources they need, whether the main source is from family or friends. Sulloway focused on the Big Five model of personality which includes the following five basic dimensions: conscientiousness, agreeableness, extraversion, openness to experiences, and neuroticism. In general, Sulloway demonstrated that firstborns score higher on conscientiousness than laterborn siblings as they often adopt the surrogate parent role as well as being supporters of the parental status quo as it befits their often privileged status as first child. Agreeableness and openness to experience are traits that laterborns score more highly on than firstborns. This facilitates strategies of negotiation and cooperation, rather than firstborn power strategies, which are likely to be more successful for smaller, less heavily parentally favored laterborns. In addition, openness to experience facilitates a willingness to embrace novelty which enables laterborns to explore novel family and social niches to find their unique roles. Its role in innovating thinking will be discussed in the following section. Extraversion is an interesting dimension in that it contains traits such as dominance and assertiveness that firstborns, secure in their authority, score high in. But it also includes sociability which laterborns score higher on as they are more inclined to find pleasure in the developing of close social ties, a strategy that

serves them well in seeking social support outside their immediate family.

Evidence Presented in *Born to Rebel*: Birth Order and Scientific Revolutions

There is a massive amount of data in support of birth order effects presented in *Born to Rebel*, but one of the most interesting aspects is the historical evidence on birth order and support for innovative change in scientific and political thought. Sulloway documents support for innovations in science, such as Darwin's theory of natural selection, from extreme opposition to extreme support. Based on historical accounts, laterborns were 9.7 times more likely than firstborns to endorse evolution by natural selection before the *Origin of Species* was published (Sulloway 1996). Other evidence of the laterborn willingness to support controversial or radical scientific ideas includes laterborns being 5.4 times more likely to support the Copernican revolution prior to 1609, 3.1 times more likely to endorse Newtonian mechanics, 3.8 times more likely to endorse Freudian psychoanalysis, and 9.0 times more likely to endorse phrenology (Sulloway 1996). The relationships between birth order and social movements of a nonscientific nature are also documented in the latter half of Sulloway's book. For example, during the Protestant Reformation, greater support came from laterborns in comparison to firstborns. And when one examines militancy in the pursuit of radical reform, such as the black rights movement in the United States, a curvilinear relationship is seen in which the most militant reformers tend to be firstborns and lastborns while those advocating nonviolence have been middle children, such as Martin Luther King Jr.

Conclusion

Sulloway's *Born to Rebel* revived interest in examining the impact of birth order on a variety of traits and behaviors, and it did so partly by providing a solid adaptationist approach to family dynamics, personality traits, and the factors that

shape individual differences in attitudes towards scientific and political thought. It also provided an abundance of evidence from studies conducted by the author and others that demonstrated impacts on personality as seen in psychological studies in combination with historical and biographical evidence on the real world implications of birth order for supporting, or failing to support, various revolutions in scientific and ideological thought. Sulloway's book emphasized that it is not only genes that make siblings different from each other; it is also nonshared environment. In particular, he illustrated that their nonshared family niches and the adaptive strategies that are associated with them shape many sibling differences.

Frans de Waal

Sarah F. Brosnan
Departments of Psychology and Philosophy,
Neuroscience Institute and Center for Behavioral
Neuroscience, Georgia State University, Atlanta,
GA, USA

Definition

Frans de Waal is a Dutch biologist whose research demonstrates that nonhuman primates show aspects of behaviors previously considered to be exclusively in the domain of humans, such as empathy, reconciliation, and fairness, emphasizing the continuity between humans and other species.

Introduction

Frans B. M. de Waal has studied animals all of his life. As a child, he observed (or collected and then observed) any animal he could near his home in the Netherlands, developing a fascination with the behavior of all species. This ultimately led to a career studying a variety of different topics that, as a whole, demonstrate the substantial cognitive and emotional continuity between humans and other animals. In particular, he has focused on the many ways that animals negotiate with one another to avoid, minimize, ameliorate and, if all else fails, reconcile conflict to maintain their beneficial social relationships. Although his research focuses on nonhuman primates, his work is key

to understanding social behavior and cognition across the animal kingdom.

A Life Studying Primates

Shortly after receiving his PhD from the University of Utrecht in 1977, where he studied the social behavior of the chimpanzees at the Royal Burgers' Zoo in Arnhem, the Netherlands under the direction of Jan van Hooff, de Waal rose to prominence with the publication of *Chimpanzee Politics*, which followed the social relationships among the adult males of the Burgers' zoo chimpanzee colony over a 4-year period. This book, which highlighted the ways in which these apes use conflict resolution to maintain their social order, brought primates' social strategizing to the forefront, over the then dominant view that aggression controlled behavior. Moreover, foreshadowing a career that integrated ideas from other disciplines into his scientific thinking, in this book de Waal explicitly compared the chimpanzees' political behavior to the ideas introduced by Machiavelli in his book *The Prince*. While at Burgers' Zoo, de Waal was the first person to recognize consolation and reconciliation in nonhuman primates and established the methodology for their study (postconflict/matched-control; de Waal and van Roosmalen 1979). In later years, with Filippo Aureli, he further documented that while reconciliation appears to be widespread across the animal kingdom, consolation is more rarely seen, possibly indicating that it requires more advanced cognition.

In 1982, de Waal emigrated to the USA, working first as a research scientist at the University of Wisconsin, Madison, and then, 10 years later, moving to Emory University in Atlanta, Georgia, where he remains the C. H. Candler Professor of Primate Behavior in the Psychology Department and the founder and Director of the Living Links Center of the Yerkes National Primate Research Center. In the USA, de Waal's research became more experimental, with the goal of elucidating underlying behavioral mechanisms for the behaviors he had observed earlier in his career. While exploring the mechanisms underpinning the

primates' behavior, however, he maintained his focus on the animals' natural behaviors, and never forgot the importance of the observational approach. Combining experiment and observation has led to important insights. For example, continuing his exploration of mechanisms that animals use to avoid and ameliorate conflict, he and Jessica Flack demonstrated that high ranking individuals in rhesus monkey groups play a control role that helps to maintain stability in the social group (Flack et al. 2006).

De Waal was one of the early researchers to recognize the benefits of studying capuchin monkeys, a large brained neotropical species of primate sometimes referred to as the "New World chimpanzee." This species is highly cooperative in the wild, and in his earliest work with capuchins, he delved into cooperation and related behaviors. He first demonstrated that capuchin monkeys not only shared food reciprocally, but that they understood their partner's role in tasks that required joint action to obtain a reward and adjusted their decisions based upon their partner's behavior (de Waal and Berger 2000). Extending this, he and Josh Plotnick later showed that elephants, too, understood their partner's role in a cooperative task (Plotnik et al. 2011). He and Sarah Brosnan found that both capuchin monkeys and chimpanzees responded negatively to receiving a less preferred reward than a social partner (Brosnan and de Waal 2003). This was the basis for their hypothesis that the evolution of fairness is linked to the need for social partners to be able to evaluate their contribution to a cooperative endeavor relative to their partner's, in order to judge whether or not to maintain the relationship.

Social animals that can recognize themselves and their social partners should have an advantage over those who cannot, and de Waal has also explored the ways in which individuals show this recognition. He and Lisa Parr demonstrated that chimpanzees could recognize familial relationships simply by looking at photographs of unknown chimpanzees (Parr and de Waal 1999). Later, he and Jennifer Pokorny showed that chimpanzees could also recognize females by their swellings (sexual skin in the ano-genital region that becomes bright pink and swollen during the

females' estrous phase), but only for known individuals, suggesting whole body knowledge for other individuals in their social group. This work garnered them an Ig Nobel prize in 2012. Finally, he and Pokorný showed that capuchin monkeys recognize other members of their social group and, with Marietta Dindo, de Waal demonstrated that while capuchins do not recognize themselves in the mirror, they do not treat the mirror as a stranger, indicating that a more nuanced approach is needed for our discussions of self-recognition.

One advantage to living in a social group is that individuals can pass information among other members of the group. In order to better understand how these animals decide who and what to copy, with Kristin Bonnie, Victoria Horner, and Andy Whiten, he studied cultural transmission in primates (Bonnie et al. 2006). They demonstrated that, as with humans, subjects chose who to copy based on both the prestige of the demonstrator and what the other members of the group were doing, called conformity. In particular, he argues in his book *The Ape and the Sushi Master* that much social learning occurs as a result of young members of the group absorbing the behavior of older ones, much like the sushi apprentice learns from the master. Of course, animals can also explicitly share information through communication, and he and Amy Pollick explored the role of gesture in the evolution of language, studying the flexibility of both gestural and vocal signals in bonobos and chimpanzees (Pollick and de Waal 2007).

Finally, de Waal was one of the first scientists to consider whether social behavior in primates is underpinned by empathy, and he and Stephanie Preston developed an influential hypothesis to explain the origins and evolution of empathy (the Perception-Action Model; Preston and de Waal 2002). De Waal has since demonstrated that both capuchins and chimpanzees will give prosocially to other members of their group and that these effects are mediated by factors such as the inequity of the outcome, the degree of relatedness of the partners, and the behavior of the potential recipient. Most recently, he has returned to his roots studying consolation behavior, this time in rodents; he and collaborators Larry Young and James Burkett demonstrated that the consolation

behavior in prairie voles is most likely underpinned by empathy.

De Waal has accomplished much; to date, he has been on the editorial board or editorial staff of 15 journals, is currently a Review editor for *Science* and the Editor-in-Chief of *Behaviour*, and has published more than 150 peer-reviewed papers, 100 chapters, and 75 commentaries in multiple languages. He is a member of the US National Academy of Sciences and the Royal Dutch Academy of Sciences, a Fellow of the American Academy of Arts and Sciences and the Japan Society for the Promotion of the Sciences, and the recipient of two *Doctor Honoris Causa* degrees and the American Society of Primatologist's Distinguished Primatologist Award. In 2013 he was appointed as Distinguished Professor at the University of Utrecht.

Aside from his research, in what he describes as a "second career" (de Waal 2009), de Waal has done much to promote scientific interest and literacy in the public. He had written 13 books on primate behavior and edited an additional 10, with the goal of bringing the science of primate social behavior to the public. His most recent book, *Are we smart enough to know how smart animals are?* is representative, challenging people to reconsider what we consider to be "intelligence" in other species by dropping our anthropocentric assumptions and taking into account the environment in which the animal evolved (that is, what sort of intelligence the animal needs in order to survive and thrive). Aside from his books and lectures, his TED talk on the evolutionary roots of morality has become an Internet sensation (http://www.ted.com/talks/frans_de_waal_do_animals_have_morals.html). Outreach such as this has led to him being recognized as one of *Discover* magazine's "47 All-time Great Minds in Science" and *Time* magazine's "100 Most Influential People."

Conclusion

Frans de Waal has done more than perhaps any other primatologist to demonstrate the continuity between humans and other species. He was one of the first scientists to seriously argue for the

presence of empathy in other species, and his research in that area has been ground breaking. De Waal has also shared his passion for nonhuman species with the public, writing more than a dozen best-selling science books about primates and other animals and giving innumerable talks and presentations, including a very successful TED talk. As a result, he is one of those rare scientists whose work has influenced both scientists and nonscientists alike.

Definition

This 1982 book by Frans de Waal follows the 4-year power struggle among a group of chimpanzee males, documenting the complexity of their social lives and offering up a lesson on the importance of understanding other species' behavior to understand the evolution of human behavior.

Introduction

If Shakespeare had focused his political plays on chimpanzees rather than British royalty, *Chimpanzee Politics* would likely have been a plot he relished. The interactions among the chimpanzees, masterfully conveyed by de Waal, include overthrows, shifting alliances, and the murder of the former ruler. This fascinating book follows several years in the lives of a group of

chimpanzees housed at the Royal Burger's zoo in Arnhem, the Netherlands, documenting their social lives and, in particular, the power struggle among the group's males. Through his approach, readers are not only drawn into the saga, but come away understanding how to study behavior in other species and why it is so critically important for understanding the evolution of human behavior.

Power and Dominance in Chimpanzee Society

One of the most notable things about *Chimpanzee Politics* (de Waal 1982) is the approachable way in which it was written. Rather than diving immediately into a dry account of the interactions between the animals, de Waal carefully sets the stage, allowing the reader to fully understand the ensuing story. He first introduces the characters, then considers their behavior. Throughout it all, de Waal is careful to separate the observations of each event from his interpretation of those events, which allows readers to understand where his assertions come from and then draw their own conclusions based on the observations. No less important is the inclusion of hundreds of photographs of the chimpanzees and behaviors that de Waal is discussing, most by de Waal himself; there is barely a page without at least one photograph. This is highly unusual in scientific books, but the impact is profound. The pictures allow the reader to create that essential mental image of the situation that enables them to not just read about, but mentally see, the narrative as it plays out.

After the stage is set, de Waal describes a 4-year period during which the reigning alpha male, Yeroen, is dethroned by the upstart Luit and then forms a 3-year alliance with the now second-ranking male, Nikki, that allows the two of them to dominate the more powerful Luit. Nikki benefits by being the king, and Yeroen benefits by maintaining substantial power despite his lower dominance – in fact, a key point throughout the book is that in politics, rank and power are not synonymous, a point as relevant to human society as it was to Yeroen, Nikki, and Luit. Yeroen maintains many of the benefits of

rank, including relatively more free mating privileges than would be expected of an otherwise third-ranked male. It all falls apart 3 years later, quite literally overnight, when, for reasons unknown, but likely relating to Nikki's increasing intolerance of Yeroen, the alliance disintegrates. With the ruling males' sudden break, Luit immediately regains his position as the unchallenged alpha male. Although the original book ends here, the twenty-fifth anniversary edition adds an Epilogue that completes the story; ten short weeks after Luit became the alpha male, Yeroen and Nikki reunite for a single battle that kills him. They remove fingers, toes, and testicles, leaving him dead of blood loss. Shortly thereafter, young Dandy, who had previously been excluded from the males' intrigues, joins the dominant male triangle as the alliances shift again.

The story itself is captivating, but its scientific importance lies in its value as a record of this social group's dynamics. De Waal was able to acquire an astonishing amount of detail over an extended period of time (more than 4 years). This is due in part to his exceptional skills as an observer and in part to the fact that he was able to observe the group so intensively for such a long time frame. Although other longer-running studies exist, particularly in the wild, de Waal was able to get this level of detail because this is a captive group (albeit in a very large space), so he could see most of the animals most of the time, allowing for a level of completeness that is unprecedented. As a result, he knew who groomed whom, who mated with whom, who deferred to whom, and how the relative levels of these activities varied across the different manifestations of the dominance hierarchy during these 4+ years. Although correlations drawn from observations can never indicate causation, the degree of documentation is sufficient that the full picture emerges, allowing speculation about not only the animals' actions but also their motivations. Moreover, because this is such a large population, including multiple adult males (a rarity in most captive populations), the dynamic is more complex than can typically be obtained in a captive population.

Prior to the writing of this book, almost all scientists studying animal behavior based their analyses and interpretations on tallies of events

and behaviors that had occurred in the group. De Waal does the same – throughout the book, he discusses frequencies of grooming or aggression and displays charts of how these various behaviors altered depending on who was currently dominant – but he subsidizes this approach with historiography. In this, his goal is to understand the details of what happened in the group during these periods of social instability. To do so, he also relies more heavily than most on anecdotes. There is a saying in science, used to disparage one-off observations, that “the plural of anecdote is not data,” but de Waal takes issue with this when it comes to key events that are not replicated because there is no way for them to be replicated. For example, there has only been one American president to leave office under threat of impeachment (Richard Nixon, who resigned before he could be impeached for the Watergate scandal), but just because it has only happened once makes it no less important to understanding what causes the downfall of a key political official. In particular, to understand why among US presidents brought up for impeachment, only Nixon fell from power, it is instructive to compare his story to those of the only other two attempted impeachments of US presidents, which were not successful (Andrew Johnson, in 1868, for violating the Tenure of Office act following the suspension of Secretary of War Stanton and Bill Clinton, in 1998, for perjury and obstruction of justice following his statements regarding his relationship with Monica Lewinsky). The power of anecdotes for understanding rare events is no less true with chimpanzees; the fact that the Yeroen–Nikki coalition was unique does not make it any less important for understanding what happens in chimpanzee male social interactions.

Although the book is written at a level to be enjoyed by a general audience, this was also the first book to widely introduce several of de Waal's scientific ideas. For instance, it is here that he first brings the idea of the minimally winning coalition to studies of chimpanzees and emphasizes its role in understanding power dynamics. He also provides the data to support a disambiguation of dominance and power. As he shows, the individuals who are at the top of the dominance hierarchy, as evidenced by the direction of formal

subordination signals (i.e., the pant grunt in chimpanzees) are not always the ones who have the power in the group, as evidenced by who is allowed to mate, who intervenes in fights, and who has the support of the other key chimpanzees (i.e., the alpha female). Finally, in this book, de Waal makes a claim that verges on shocking in today's society, which is that the dominance hierarchy is not always a bad thing. As he shows, the worst fights and the highest levels of stress occur when the dominance hierarchy is unstable. When rank is clear, there is nothing to fight over; each individual knows their place, and days can go by without a fight, even in the presence of otherwise conflict-inducing events, such as an estrous female. However distasteful this may be in our society that strives for egalitarianism, this insight provides insight into the causes of conflict and instability among humans.

Throughout, de Waal repeatedly emphasizes the links between chimpanzee and human behavior. This likely causes strong reactions in almost everyone, ranging from those who find these links obvious to those who are horrified, either at the audacity of his attempt to level the playing field between humans and chimpanzees or his willingness to imbue these nonhuman creatures with motives, planning, thought, and other hallmarks of higher-order cognition. No matter what the reaction, it is in this way that the book is perhaps its most important, by reminding readers that humans are also products of their biology and their evolutionary history. Whether it causes the reader to reevaluate his or her position in the state of nature or work harder to understand the antecedents of human-specific cognition and behavior, this understanding is critical for fully understanding human behavior.

Conclusion

De Waal has written an astonishingly large number of very well-received books for any author, much less one who has simultaneously led a productive research career. What is it about *Chimpanzee Politics* that causes it to stand out? It has never been out of print and is now in the twenty-fifth anniversary edition. Not only is it routinely cited by

academics, but it is well known in the nonacademic world; then-US Speaker of the House Newt Gingrich reportedly put it on his recommended reading list for freshman representatives. Part of it is likely the story itself. This is not a dry textbook about animal behavior; this is, at heart, a narrative about Yeroen, Nikki, Luit, Mama, Gorilla, and the other chimpanzees. The aforementioned inclusion of photographs throughout the book reinforces this by giving the reader faces to put with names and a mental image of the various behaviors that de Waal discusses. Part of it is the balance between data and narrative; de Waal conveys the story, but never loses sight of the data that underpin it. The rest is the obvious connection between these apes and humans. The narrative rises above a discussion of chimpanzee politics and allows the readers to see human behavior, as reflected in the lives of these chimpanzees.

Glossary of Terms

Anthropology The study of humans and their societies in the past and present.

Anthropometry	The study of measurements and proportions of the human body.
Apperception	The perception of a new experience in relation to a past experience.
Archaeology	The study of past human activity and populations through material remains.
Cross-sectional data	Data collected by observing many subjects at the same point in time for a single observation per subject.
Diffusion	The spread of an idea or item from one culture to another through interaction.
Ethnocentrism	The belief that one’s own culture is more valuable or superior to another.
Ethnography	The study of a single group through direct contact with the culture.
Ethnology	A branch of anthropology that compares and analyzes the characteristics (e.g., origins, languages, customs, traditions) of different groups and the relationships between them.
Folklore	Traditional art, literature, knowledge, and practices that are passed on largely through oral communication and example.
Habilitation	A postdoctoral qualification that requires a thesis written at a professorial level based on completely independent research.
Independent innovation	When a culture forms an idea without any influence from another culture.
Linguistics	The scientific study of language: form, meaning, and context of languages.
Longitudinal study	A research design that involves repeated observations of the same variables in the same subjects over long periods of time.

Migration	The movement of people from one place to another with the intention of settling in the new location might be temporary or permanent.
Mythology	The collection of stories that a group of people tell to explain nature, history, and customs.
Phonemes	Units of sound in a language.
Phonetics	The study of the sounds of human speech, their physiological production, acoustic properties, auditory perception, and neurophysical status.
Physical anthropology	The branch of anthropology concerned with the biological and behavioral aspects of humans, their living relatives, and their extinct ancestors.
Psychophysics	A field that examines how organisms perceive their environment through their senses.
Salvage ethnography	The recording of practices and folklore of cultures threatened with extinction as a result of modernization, assimilation, or acculturation.
Stratigraphy	A branch of geology that studies rock layers (strata) and layering in order to lend context and place artifacts in sequence.
Teleology	Implies a purpose, directive principle, or goal; in this case, all stages are moving toward the goal of civilization.

Definition

Franz Boas (1858) is widely known as the Father of American Anthropology and pioneer of the

four-field approach to anthropological research. His highly influential research career spanned each of the four subfields of anthropology, uniting them under one common goal – the holistic study of man. Modern methods in subjects as varied as human growth studies and folklore studies were introduced or reinvigorated by his adherence to scientific rigor and his innovative approach to cultural studies using his concepts of historical particularism and cultural relativism. The Boasian tradition lives on in the modern anthropological research and his later-in-life devotion to the education and professional development of students.

Introduction

Franz Boas (1858–1942) was a German-born American anthropologist and widely considered the “Father of American Anthropology.” An innovative and productive researcher, Boas is credited with a critical restructuring of anthropology that introduced culture as a central concept in anthropological research, emphasized more rigorous scientific methods, and advocated for academic and professional development. He was one of the most influential anthropologists of his time, espousing a holistic approach to the study of man that unified four subfields (physical anthropology, cultural anthropology, linguistics, and archaeology) under one overarching goal – to define the human species in totality. His four-field model of anthropology and his pioneering research in each subfield had a significant impact on modern anthropology.

Boas challenged traditional views of racial categories and cultural evolution with the introduction of cultural relativism and historical particularism to anthropological research. He made innovative strides in methodology for the study of linguistics, ethnology, human growth, migration, folklore, mythology, and environmental plasticity. However, his research contributions only comprised a portion of Boas’s influence, as his most lasting legacy was his efforts in educating students that would go on to become prominent anthropologists that carried on his Boasian tradition.

Early Life and Education in Germany

Franz Uri Boas was born on July 9, 1858, in Minden, Westphalia, Germany. As a young boy, Boas developed an interest in nature and exploration, with a specific fascination with zoological and geographical topics (Cole and Boas 1999). Boas attended the University of Heidelberg and the University of Bonn to study mathematics, physics, and geography. At the University of Kiel, Boas graduated with a PhD in physics with a minor in geography in 1881. His dissertation, “Contributions to the Understanding of the Color of Water,” was in the field of psychophysics. After graduating, Boas entered the military for a mandatory year (Cole and Boas 1999).

After his military service finished, he began planning an Arctic expedition that would redirect his career path toward anthropology and shape his academic research and interest in the First Nations of the Pacific Northwest. To prepare, Boas studied Danish, English, and Eskimo (Inuit) languages, cartography, astronomy, and anthropometry (Cole and Boas 1999). The focus of the expedition was the unexplored Baffin Island in Canada that was inhabited by the Inuit (Knötsch 1993).

In 1883, Boas set off to Canada to investigate the relationship between Inuit migrations and the physical geography of their region (Knötsch 1993). Boas’s time with the Inuit was eye-opening. Though geographic articles were funding his expedition, his ethnological articles surpassed the geographic articles in number. Boas collected extensive ethnographic research that would later become a monograph, “The Central Eskimo” in 1888 (Chapman and Routledge 2005). Boas recognized a great urgency to study indigenous people in Canada before the European assimilation and the projected loss of languages and customs (Cole and Boas 1999).

Ethnology began to take the forefront when Boas returned to Germany. At the University of Berlin, Boas pursued habilitation with the thesis Baffin-Land in 1885 (Cole and Boas 1999). He also worked as an assistant in the Royal Ethnological Museum. He associated with several anthropologists and met two Bella Coola Indians

from British Columbia. Their dance and language fascinated him, and by 1885, Boas had committed to anthropology as his primary field of study. He began planning an expedition to British Columbia that would be the first of many throughout his career and establish a lifelong relationship with the Native Americans of the Pacific Northwest (Chapman and Routledge 2005; Cole and Boas 1999).

Boas in the United States

Boas traveled to British Columbia for the first time in 1886, and on a return trip through New York, he was offered an assistant editor position at *Science* magazine. For personal and political reasons, Boas had been looking for an opportunity to move to the United States so he accepted the offer and soon after, married his fiancée, Marie Krackowizer (Cole and Boas 1999). They would go on to have six children, one of whom died in infancy.

In 1888, the British Association for the Advancement of Science (BAAS) asked Boas to go on an ethnological expedition to British Columbia that turned out to be the first of many BAAS-funded expeditions to the Pacific Northwest (Strazny 2013). Around the same time, Boas started teaching at Clark University where he would create the first department of anthropology in America, head the department in 1889, and graduate the first American PhD in anthropology, A. F. Chamberlain. He ended his tenure at Clark University in 1892 (Cole and Boas 1999).

After a few productive BAAS-funded expeditions, particularly focused on linguistics and the Kwakiutl, Boas became involved with the Chicago World’s Fair. From 1892 to 1894, he was hired as chief assistant of anthropology at the World’s Columbian Exposition under Frederic Putnam, the director and curator of the Peabody Museum at Harvard University. Boas used Kwakiutl to represent the Pacific Northwest in the exhibition, and after the World’s Fair ended, he was hired to organize the material into a museum that would later be called the Field Museum of Chicago (Cole and Boas 1999).

Boas would follow his experiences in Chicago with the most intensive ethnographic fieldwork of his career, a 3-week stay among the Kwakiutl of British Columbia. In 1896, upon his return from the field, Boas joined Putnam in New York as an assistant curator of ethnology at the American Museum of Natural History (AMNH) and also joined Columbia University as a lecturer in physical anthropology. By 1899, Boas had become a professor of anthropology at Columbia University, and in 1901, he transitioned to a curator position at AMNH (Chapman and Routledge 2005; Cole and Boas 1999).

At AMNH, he convinced Morris Jesup, the president of AMNH, to support an ambitious 5-year major research investigation of the people of the Pacific coasts of America and Asia before the populations disappeared. The scope of the Jesup North Pacific Expedition was international and involved the collaboration of professional and reliable researchers. The project required considerable organization by Boas as it ran from 1897 to 1902 (Cole and Boas 1999; Lewis 2001). As the project came to a close, Boas was starting a new phase of his life – the pursuit of education and overhauling of anthropological theories, concepts, and methodologies starting at Columbia University.

Boas resigned from AMNH in 1905 and turned his focus to promoting the academic and professional development of anthropology. He established anthropology at Clark University and would go on to establish the first PhD program in anthropology at Columbia University in 1908 (Moore 2000). He was active in multiple scientific organizations, including the American Anthropological Association, the *International Journal of American Linguistics*, the American Ethnological Society, and the American Folklore Society, and he led the founding of a new national anthropological society – the American Anthropological Association and an *American Anthropologist* journal attached to it (Strazny 2013).

Boas established Columbia University as the center of the new century's professional anthropologists, and soon Columbia and Boas were changing the face of the American anthropology.

Boas influenced some of the most prominent figures in the American anthropology, including Margaret Mead, Alfred Kroeber, Ruth Benedict, Robert Lowie, Edward Sapir, and F. G. Speck (Moore 2000). Throughout these processes, Boas maintained a rigorous schedule of his own scientific work and continued publishing in many areas of anthropology even after his retirement, and an emeritus status was given in 1938 in Columbia.

Four-Field Anthropology

Boas is perhaps best known for his four-field model of anthropology, where anthropology is composed of four subfields: cultural anthropology (ethnology), linguistics, physical anthropology, and archaeology. This concept differed from the European tradition in which linguistics and social anthropology were separate fields of study. The four-field tradition was launched by Boas at Columbia University, and his students would establish four-field anthropology in universities across the United States (Jacknis 2002).

In 1904, Boas introduced the four-field model as an approach that would produce a holistic understanding of what it meant to be human by uniting different anthropological research (Boas 1904). The realm of anthropological knowledge was defined as “the biological history of mankind in all its varieties; linguistics applied to people without written languages; the ethnology of people without historic records; and prehistoric archaeology” (Boas 1904). Each subfield contributed knowledge to the holistic study of man, and Boas stressed the integration of multiple perspectives: cultural history, material culture, anatomy, social organization, customs, folklore, grammar, language use, and population history.

Boas contributed to all four branches of anthropology in wide-ranging and diverse projects. His contributions bore the hallmarks of the Boasian tradition: rigorous scientific methods, an emphasis on empiricism, and an understanding of how perception can affect the object of study. Alfred Kroeber, Boas's first student, outlined the three empirical principles of the Boasian

anthropology – that science must begin with questions, not answers; that science must be dispassionate and unbiased in the search for truth; and that sweeping generalizations are out of place in a natural world ruled by variation (Kroeber 1949). Boas put the search for truth above all else and trained anthropologists to follow rigorous scientific standards and only formulate conclusions after thorough and extensive data collection (Jakobson and Boas 1944; Lewis 2001).

Cultural Anthropology (Ethnology)

Ethnology was a main pillar of Boas's fieldwork in the Pacific Northwest, and he would spend over 50 years of his life devoted to understanding the cultures of the Native American groups, particularly the Kwakiutl, in order to provide a comprehensive archive of these rapidly dwindling cultures (Chapman and Routledge 2005; Cole and Boas 1999; Lewis 2001). His efforts to develop fieldwork techniques, train natives to act as informants and investigators, record native texts, and gather all relevant views from the natives themselves would lay the foundation for the American ethnology. Boas believed that ethnology would be a vital aspect in the critical analysis of unique cultures in anthropological research (Boas 1940).

Boas was motivated by a sense of urgency in the efforts to capture Native American cultures and languages before they vanished. Today, this approach is known as "salvage ethnography," and the premise is that documentation will preserve a dwindling culture's rituals, beliefs, and customs in perpetuity (Erickson and Murphy 2008). Boas embodied this mentality and spent years returning to British Columbia and gathering and recording extensive information on Native American cultures that were threatened by expanding Euro-American influence (Chapman and Routledge 2005).

Boas introduced culture as the primary concept for describing differences in behavior and thought between human groups and gave it a place of prominence as a central analytical device in anthropological research (Moore 2000). Culture,

to Boas, was composed of thousands of activities and modes of thought that constitute a group's daily lives. These thoughts and behaviors were largely unconscious, learned from birth, and caused an individual to act in conformity within the group (Boas 1911b). Culture remained unconscious unless confronted by a different way of life or inhibited from expression (Boas 1940; Stocking 1966).

In the Pacific Northwest, Boas was interested in evaluating diffusion versus independent innovation of cultural ideas. Boas provided an example of agriculture, which developed at the same time in the Americas and Asia, but without transoceanic communication, it is considered independent innovation (Boas 1940). Boas was interested in tracking the diffusion of customs and rituals through neighboring tribes down from the Bering Strait, but with the base assumption of independent innovation. Empirical proof of diffusion required systematic and extensive data collection of every element of culture (Boas 1940).

Boas introduced two critical concepts to ethnological research: historical particularism and cultural relativism. Historical particularism is the idea that each society has a unique history that informs its cultural development. Boas rejected the prevailing idea of a deterministic and unilineal evolutionary path, where all societies evolve teleologically through the same universal stages, from primitive to civilized (Boas 1940). The use of generalities and universal laws masked the truth of a culture, so Boas argued that cultural traits needed to be explained within their own specific cultural contexts because each culture had a unique and different history (Moore 2000).

Cultural relativism is the idea that a person's activities or beliefs should be understood in the terms and values of their own culture, not the observer's culture (Boas 1911b, 1940). Boas opposed the ethnocentrism of the European anthropology and argued that biased perceptions based on the ethnographer's own culturally acquired norms skew the true understanding of a culture. Cultural relativism required an insider's perspective through data collection, integration

and interaction with members of the culture, and analysis of the unique cultural history. Boas moved away from the singular “culture,” as something humans possess to varying degrees or stages, toward the plural “cultures” with different but equal potentials (Stocking 1966).

In Boas’s seminal work, *The Mind of Primitive Man* (1911b), his thesis argued that assertions of the mental superiority of Europeans over Native Americans could be traced to differences in culture – the unconscious traditions and customs that govern all individuals’ thoughts, actions, and choices since birth (Stocking 1966) – and the flawed and biased perceptions of the anthropologists observing these mental differences. Boas showed that Native Americans exhibited the same mental powers of abstraction, inhibition, and choice as civilized Euro-Americans and that the daily behaviors and thoughts that constitute culture are as numerous in Native American culture as they are in the European culture (Boas 1911b; Stocking 1968). Boas’s principles of systematic and unprejudiced evaluations of culture within their specific context and valuing fieldwork and cultural history recordings would shape ethnographic practices across America.

Folklore and Mythology

In his ethnological fieldwork, Boas developed a passion for collecting folklore, mythology, and art from the Pacific Northwest (Boas and Tate 1916). Boas recognized the central and important functions of folklore and mythology in rationalizing traditional cultural behaviors and expressing native values and thoughts (Boas and Tate 1916; Stocking 1966). He worked to professionalize the study through scientific methods and championed the use of extensive research, fieldwork, and strict guidelines for scholarship. His continued scholarship promoted the complexity, diversity, and functionality of folklore, mythology, and art within a culture, opposing the prevailing views that dismissed these forms as simplistic or non-functional through the lens of ethnocentrism (Boas 1940; Chapman and Routledge 2005).

Linguistics

Linguistics took an early and prominent place in Boas’s fieldwork as much because of the urgency of documenting the disappearing Native American cultures as his sincere fascination with the languages of British Columbia (Jakobson and Boas 1944). Boas sought to understand and preserve these indigenous languages, and he brought his characteristic scientific rigor to linguistic description. He believed that languages were an important tool for ethnographic fieldwork and produced an extensive body of valuable linguistic descriptions of numerous indigenous languages, including Tsimshian, Chinook, Tlingit, and Kwakiutl (Chapman and Routledge 2005; Strazny 2013).

His first major contribution to linguistics was “On Alternating Sounds” (1889). The paper addressed the phenomenon of “alternating sounds,” or speech sounds that were vague, that linguists thought signaled the linguistic inferiority and lower evolutionary stage of Native Americans (Strazny 2013). Boas argued that this was not an issue of language, but with linguists recording languages with radically different phonetic systems than their own native language. The linguists were apperceiving the sounds of the indigenous languages and the different speech sounds translated into a misunderstanding of the sounds (Boas 1889).

In 1911, Boas wrote an introduction to the *Handbook of American Indian Languages* (1911a) where he laid out an approach that sought to eliminate every linguistic prejudice that had thus far limited the systematic and thorough discovery of indigenous linguistic phenomena. Boas’s empiricism meant describing and analyzing languages from an insider’s perspective, not through the figurative “blindness” of a linguist’s native language. Each new language should be approached without preconception or rigid attachment to a familiar grammatical and phonemic structure. Applying ethnological concepts, Boas also argued that each language was a unique representation of the speakers’ culture and there was no inherent superiority of languages (Boas 1911a; Jakobson and Boas 1944).

Boas endeavored to find the “inner form” of a language that would capture unconscious categories that could then be used to analyze that particular language. Each language chose different ways to express concepts (e.g., by simple terms or combinations of terms, by related or unrelated terms), and Boas presented the system of phonemes and grammatical devices as a necessary base for linguistic analysis (Jakobson and Boas 1944). Boas uncovered universal elements among diverse linguistic structures that suggested they were necessary elements in every language’s grammar and phonemics (Jakobson and Boas 1944; Strazny 2013).

In order to study diffusion, Boas introduced a comparative aspect to his linguistic studies and noted that unrelated but contiguous languages manifested common grammatical and phonemic characteristics (Jakobson and Boas 1944). He found evidence of borrowing of linguistic elements and language mixture between groups and that languages could develop as convergence from diverse sources or divergence from a common origin (Strazny 2013). These revolutionary findings and his two seminal works had a major impact on linguistics, causing a fundamental shift in how linguists approach new languages and analyze the organization and production of sounds.

Physical Anthropology

Boas pioneered many efforts within the field of physical anthropology as a result of his interest in understanding human variation and its connection to the environment, race, migration, and genetics. His contributions debunked the idea of racial fixity, established a design for migration research, introduced the concept of environmental influence on human biology, and uncovered significant discoveries about human growth (Little 2010). Physical anthropology continues to draw on the series of innovations in statistics and research design that are a lasting legacy from Boas.

Boas drew on his knowledge of statistics, anthropometry, and natural sciences as he began exploring factors influencing human biological

variation (Little 2010). In 1888, Boas made his first overture in the study of human growth using previously collected data (Tanner 1959). He discovered that variation in height during adolescence could be explained by individual variation in growth rates, or as he called it “tempo of growth” (Little 2010; Tanner 1959). The finding of “tempo of growth” led Boas to question the statistical validity of cross-sectional designs of growth studies (Boas 1892; Little 2010).

Boas spearheaded the first American longitudinal growth study, which represented a significant breakthrough in the field of human growth studies (Tanner 1959). In 1891, he conducted a longitudinal survey of local children and showed that variability at adolescence was reduced when chronological age was replaced by “time of peak velocity,” which was the beginning of the concept of physiological or developmental age as distinct from chronological age (Boas 1930).

Boas would publish numerous papers on the topic of growth studies and introduce biostatistics to physical anthropology. Five of his most important contributions to the field of human growth studies were (1) the production of the first National Growth Standards, (2) the introduction of the concept of physiological or developmental age, (3) the evidence of the impact of social and environmental conditions on growth, (4) the establishment of a link between “age of peak velocity” and measures of physical size during adolescence, and (5) the discovery of a secular trend in growth (Boas 1892, 1930; Little 2010; Tanner 1959).

In 1908, Boas initiated a migration study to examine the impact of migration on human biological characteristics and to address the idea of fixed races, a prevailing idea in mainstream anthropology that humans could be divided into a fixed number of pure races and that these rigid groupings corresponded to biological differences in personality, intelligence, and capacity for culture (Little and Kennedy 2010). He began with a pilot study in New York and expanded it to more than 18,000 subjects from different ethnic groups (Boas 1911b, 1912a; Tanner 1959). Boas employed a simple study design that compared parent-child measurements in cases of children

born before immigration and cases of children born after immigration to the United States (Little and Kennedy 2010; Tanner 1959).

One of the main traits that Boas investigated was the cephalic index, a measure of head form that is the ratio of skull breadth to width. The cephalic index was considered a stable, hereditary trait that linked fixed races with intelligence differences. Boas found significant differences between the children born pre- and post-immigration in the cephalic index, suggesting significant variation in cephalic index within groups or “races” (Boas 1911b, 1912a; Little 2010). He additionally found that the use of statistical averages could not be used to distinguish fixed races empirically and that the averages of different races showed little difference compared to the large range of variation that existed within races (Boas 1911b; Little 2010).

This was not Boas’s first attack on the fixed race concept. One early example was *The Half-Blood Indian* (1894), in which Boas challenged the current assertions that a “hybrid” race would exhibit decreased fertility, increased mortality rate, and likely physical and mental deficits (Boas 1894). He examined 16,000 Native Americans and demonstrated that the fertility and stature of children born of different races actually surpassed that of either parental population (Lewis 2001).

In *The Mind of Primitive Man*, Boas argued that these results proved that human variation was complex and unrecognized by traditional fixed race categories, invalidating race as a biological concept that could be used to classify the intelligence or superiority of a group of individuals in comparison to another group (Boas 1911b; Little 2010). Boas moved the focus from the “fixed races” as an explanation for human variation to the role of the environment in shaping physical characteristics and the plasticity of human biology in response to environmental factors (Little 2010; Mascie-Taylor and Little 2004).

The findings of his migration study were confirmed with later work that used Boas’s migrant research design and found similar changes among Japanese migrants to Hawaii, Mexican-American migrants, and Chinese migrants to America (Little 2010; Mascie-Taylor and Little 2004). Boas’s

study would become a model for future migration studies and investigations into the impact of environment, migration, and environmental plasticity, and human growth studies continue to use Boas’s longitudinal research design and statistical methods of analysis.

Archaeology

Boas’s contribution to archaeology was limited compared to his contributions to the other subfields, but no less important. At the turn of the century, Boas was increasingly concerned with the state of the American archaeology which was dominated by amateurs, lacked rigorous methodology, and was largely a descriptive and classificatory discipline. An opportunity in Mexico gave Boas the chance to leave a lasting impression on Central American archaeology (Godoy 1977).

From 1910 to 1912, Boas took a sabbatical to Mexico to collaborate on the establishment of the International School of American Archaeology and Ethnology (Godoy 1977). The endeavor had several objectives: (1) to expand fieldwork of Native American cultures beyond the southern border to continue the investigation of the diffusion of culture (Boas 1912b), (2) to increase the quality of archaeological and ethnological investigation, (3) to create a professional institution dedicated to scientific research that was economically independent (Stocking 1968), and (4) to educate Mexican archaeologists to carry on research after Boas’s departure (Godoy 1977).

The most significant project undertaken was the establishment of a chronological sequence for the large diversity and number of pottery fragments found in the Valley of Mexico. Under Boas’s direction, stratigraphic techniques were used to systematically investigate the geological sequences of strata for the first time in the American archaeology. Concurrently, in the Boasian tradition, anthropologists were analyzing grammar, structure, and distribution of Mexican languages and the impact of European colonization on language and culture (Godoy 1977). This would lay the foundation for modern Central American archaeology.

Social and Political Activism

As an established leader of the American anthropology, Boas was an outspoken activist in social and political issues surrounding human rights, equal opportunities, defeat of prejudice, and war (Lewis 2001). His engagement with the political sphere was motivated by a series of person core values that bridged the gap from his anthropological research to the public sphere: (1) the use of science to pursue “truth” and improve the human condition (Bunzel 1962), (2) equal rights and opportunities for everyone (Boas 1911b), and (3) rejection of the prevailing assumption that one culture was superior to others (Boas 1911b).

At the turn of the century, Boas became more directly involved in the “race problem” in America. He was drawn to the plight of African American intellectuals, like W. E. B. Du Bois, and he argued that “Negro” performance was inferior because of the conditions of slavery, but they were just as capable of culture as Europeans. Boas would become involved with the NAACP (National Association for the Advancement of Colored People) and regularly speak out against racism and encourage the study of African and American Negro culture (Hyatt 1990; Lewis 2001).

Boas’s book, *The Mind of Primitive Man* (1911b), where he laid out his arguments against the inherent superiority of civilized man over primitive man, was widely read and influential (Bunzel 1962; Lewis 2001). It would lend support and ammunition for activists fighting against Jim Crow laws, racially based on immigration restrictions and inequalities in rights and opportunities (Lewis 2001).

During World War I, Boas vocally opposed the American involvement in war and disapproved of the increasing xenophobia against Germans and the German culture as a result of the war (Lewis 2001). In 1919, he was involved in a scandal in which he published a letter titled “Scientists as Spies” that decried anthropologists that went into the field as spies under the cover of science. This move would negatively impact his positions in the AAA and the National Research Council (Hyatt 1990; Stocking 1968).

Postwar, Boas continued to speak out against racism, imperialism, and colonialism, particularly

as the Great Depression and the rise of Nazism in Europe grew more concerning. He combatted Nazism and all it stood for early on, fighting their racial ideas until his death (Lewis 2001). On December 22, 1942, Boas held a luncheon in honor of his colleague, and after concluding a speech against all forms of racial prejudice, he fell back into his chair and died. His last words were that “racism is a monstrous error or an impudent lie” (Lewis 2001).

Conclusion

Boas has had an enduring influence on anthropology. By the end of his life, he had written six books and more than 700 monographs and articles. He held many honorary degrees and honorary memberships from dozens of institutions and academic associations and served as president to some of the largest anthropological associations in America. Many of Boas’s original discoveries and methodological contributions hold up to modern scrutiny. Today, nearly all anthropologists accept the necessity of Boasian empiricism and the use of methodological cultural relativism in anthropological research.

Boas’s work with Native Americans in the Pacific Northwest inspired generations of anthropologists to study and record vanishing cultures with a firm commitment to field research that involved living among the group, learning the local language, and developing relations with native informants. Outside of academia, Boas spoke out continually against racism and racial prejudice, playing an important role as a scientist bridging the divide between academic and public spheres to communicate his research findings and affect social change. In the words of Boas’s student, Alexander Lesser, “his scientific legacy is the modern science of anthropology; his greater legacy the manner in which he changed our conception of man.”

FBO

Definition

Fraternal birth order (FBO) refers to the birth order of sons within a family – whether, for example, a boy is the oldest, youngest, or middle child among his brothers. The number of sisters is irrelevant to fraternal birth order. The fraternal birth order (FBO) *effect* refers to a consistent finding in men's sexual orientation, such that gay men have a greater number of older brothers compared to heterosexual men.

Introduction

In the search for clues about the development of sexual orientation, psychologists Ray Blanchard and Anthony Bogaert published a seminal paper in 1996 on the association between birth order and sexual orientation in men. They found that in a sample of 302 gay men, matched on year of birth with 302 heterosexual men, number of older brothers was associated with being gay. Older sisters, younger brothers, younger sisters, and age of parent at time of birth of the men were not related to sexual orientation. Also, each additional older brother increased the odds of being gay by 33 %.

The Fraternal Birth Order Effect and Its Origins

Blanchard and Bogaert's (1996) finding came to be known as the fraternal birth order (FBO) effect because of the specificity of the effect to older brothers and to men's (and not women's) sexual orientation (e.g., Bogaert 1997). In later research, it was further estimated that about 28 % of gay men owe their sexual orientation to the FBO effect explanation (vs. other explanatory factors in men's sexual orientation development; Blanchard and Bogaert 2004). Moreover, the reliability of the FBO effect was confirmed in a recent meta-analysis (Blanchard and VanderLaan 2015; see also Blanchard 2004 for a review).

In addition to year of birth and parental age, the FBO effect has been found to be independent of other potential confounds: age, socioeconomic

status, and sibship size (e.g., VanderLaan and Vasey 2011). Also, the original FBO effect (Blanchard and Bogaert 1996) has been replicated numerous times, including by independent researchers (see Blanchard 2004; Bogaert and Skorska 2011 for reviews) and in diverse samples, such as in boys with gender dysphoria (Blanchard et al. 2002), although there have also been some failures to replicate the FBO effect (see Bogaert and Skorska 2011 for a review; see Blanchard and VanderLaan 2015 for a commentary on failures to replicate the FBO effect). Thus, the FBO effect seems to be a very robust and reliable finding related to men's sexual orientation.

To explain the FBO effect, an immunological explanation, also known as the maternal immune hypothesis, has been put forward (e.g., Blanchard and Bogaert 1996; Blanchard and Klassen 1997; Bogaert and Skorska 2011). According to this hypothesis, a mother's immune system is exposed and immunized to male-specific proteins that are associated with the Y-chromosome with each successive male fetus. A mother may become immunologically reactive to these proteins because her body does not possess a Y chromosome and thus does not produce such male-specific proteins. The antibodies a mother develops after each male fetus cross the blood–brain barrier of the fetus to affect specific areas in the brain associated with the development of sexual orientation. These affected brain areas would, in turn, influence the sexual orientation of the man as an adult.

Several lines of research provide evidence that the maternal immune hypothesis is plausible: transfer of material occurs from the fetus to its mother, male-specific substances cause immune responses in women, the relevant male-specific substances play a role in sexual differentiation of the brain (independent of prenatal hormones), and a maternal immune response to male-specific substances affects fetal brain development (see Bogaert and Skorska 2011 for a review of these lines of research).

Currently there is no direct empirical support for the maternal immune hypothesis. However, there have been some studies that provide indirect evidence that a prenatal mechanism is responsible for the FBO effect. First, some researchers have

found that handedness, which has been shown to be determined prenatally, interacts with FBO in predicting sexual orientation in men. Specifically, right-handed men who had older brothers were more likely to be gay, whereas left-handed or ambidextrous men were unaffected by older brothers in their likelihood to be gay. Further, the interaction with right-handedness might apply only to moderately right-handed men and not to extremely right-handed men (see Bogaert and Skorska 2011 for a review). Second, in a key study related to the origins of the FBO effect, Bogaert (2006) found that biological older brothers were associated with a same-sex orientation in men, but nonbiological siblings (e.g., adopted or step-brothers) were not associated with sexual orientation. Moreover, the biological older brothers predicting men's same-sex orientation were often raised in a different environment (e.g., a different household) than the participant, thus providing additional support for the prenatal (and not postnatal) nature of the FBO effect.

Conclusion

Thus, one of the most reliable findings in the sexual orientation field is that men who have a greater number of older brothers (i.e., a later fraternal birth order) are more likely to be gay. An immunological explanation (the maternal immune hypothesis) has been proposed as an explanation for the fraternal birth order effect. Several lines of research support the plausibility of the maternal immune hypothesis, and there is indirect support for the biological and prenatal basis of the FBO effect. Future research will likely illuminate the origins of the FBO effect, including testing of the maternal immune hypothesis.

Definition

In the contemporary free will debate, free will is often defined as a kind of control over action in virtue of which individuals can be held morally responsible for their actions just given that individuals perform those actions with understanding of the latter's moral quality (Pereboom 2016).

Introduction

Understandings of free will vary widely among philosophers and other thinkers who have studied the subject. Some have thought that free will is merely the power of an agent to do what it wills, which could be (and has been) alternatively framed as an agent's freedom from impediments to do what it wills. Others have suggested that free will is the ability through which an agent can be the ultimate source of its actions, as opposed to those actions stemming in the end from anything outside an agent's control. Since there is no clear consensus on what free will is, this entry will focus on just one conception of free will and the *contemporary* debate that surrounds it. That conception is defined in terms of *moral responsibility* (McKenna and Pereboom 2016, p. 6). Specifically, free will is said to be the causal power in virtue of which an agent can be held morally responsible for its actions "just because [it] has performed [those actions on condition that it understood their moral quality]" (Pereboom 2016, p. 2) (Pereboom [2016] refers to this as the "basic desert" sense of moral responsibility: "The desert at issue here is basic in the sense that the agent would deserve to be blamed or praised just because she has performed the action. . . and not. . . merely by virtue of consequentialist or contractualist considerations" [p. 2].) The following considers a major threat to belief in free will of this kind and responses to that threat.

The Problem of Causal Determinism

The thesis of causal determinism holds that every event, condition, or state of affairs in the universe is the necessary consequent of some antecedent event(s), condition(s), and/or state(s) of affairs, together with the laws of nature. Phrased differently, it is the view that everything in the universe inevitably or unavoidably occurs or obtains, given what has previously occurred or obtained and the laws of nature. Causal determinism is often associated with a broadly "scientific" worldview, when such a worldview is taken to posit invariant causal laws that, at least in principle, predictably

govern the behavior of all physical objects in a non-probabilistic way. (As Horst [2011] argues, it may be false that the laws of nature are all non-probabilistic. It is widely believed that phenomena at the quantum “level” of reality are genuinely indeterministic, though this does not seem to be necessarily incompatible with causal determinism at “higher” orders of reality [Caruso 2013].) An apparent corollary of this posit is that two separate physical systems with precisely identical initial conditions and characteristics will be indistinguishable with respect to all activity that they exhibit, assuming that nothing is externally introduced to one system but not the other.

Perhaps *the* central concern of the contemporary free will debate is whether causal determinism is compatible with free will. If the thesis of causal determinism is true, it follows that every action performed by every person was ineluctable from the moment the universe came to be. A number of philosophers have believed that this is at least *prima facie* a threat to free will in a number of senses, including free will as the power enabling moral responsibility in the “basic desert” sense. Those philosophers who think that free will and causal determinism are incompatible are called *incompatibilists*. Incompatibilists come in two salient kinds: libertarians and hard determinists. The former believe that free will and causal determinism are incompatible and that free will exists and the thesis of causal determinism is false. (To be sure, libertarians need not hold that causal determinism never applies to physical objects. They can maintain that humans have special causal powers, over which they have control, that at least sometimes can be the ultimate source of humans’ actions, rather than anything outside of their control being that ultimate source.) The latter believe that free will and causal determinism are incompatible and that the thesis of causal determinism is true and hence that free will does not exist. It is worth noting that the idea that the nature of causality in the universe threatens free will need not only apply if the universe is deterministic. Pereboom (2016) points out that indeterminism may undermine free will as much as determinism, in that if agents’ actions are

brought about indeterministically but emerge randomly or probabilistically, then their actions do not appear to be under the sort of agential control required for moral responsibility. Alongside incompatibilism, the other major sort of response to the apparent tension between free will and causal determinism is *compatibilism*. As the name suggests, compatibilists maintain that free will and causal determinism are in fact compatible. The term “soft determinists” is sometimes used to refer to compatibilists who believe that the thesis of causal determinism is true.

The Manipulation Argument and Compatibilism

In much of the contemporary free will debate, it would appear that compatibilists and incompatibilists have been talking past each other, insofar as they have not had the same thing in mind when they have addressed the matter of whether “free will” exists. The philosopher Daniel Dennett, for instance, although a vociferous compatibilist, was recently happy to publicly concede that free will of the sort required for “basic desert” moral responsibility does not exist (Moscow Center for Consciousness Studies 2014). That is because the sort of free will in which Dennett, and many other compatibilists, is interested is not the one needed for “basic desert” moral responsibility but just that which he thinks will allow justification of important human practices (e.g., punishment; Dennett 2015). But a number of compatibilists, such as Sartorio (2016) and Mele (2006), do assert that free will in the “basic desert” sense is compatible with causal determinism, allowing them to have real argumentative engagement with incompatibilists, who seem to hold this conception of free will much more frequently than compatibilists.

At this point what is likely the most prominent contemporary argument for hard determinism, or, more broadly, free will skepticism, can be considered, along with a compatibilist reply (the argument is not meant to address libertarians since it assumes the truth of determinism). This

argument, called the manipulation argument, is presented in its most sophisticated form by Pereboom (2016). It is a thought experiment that has one consider four cases consecutively in which an agent is causally determined to kill another agent by factors outside of the former agent's control. In the first case, neuroscientists remotely manipulate the agent's brain ("neural states") such that he is causally determined to kill the other agent; in the second case, neuroscientists program the agent's brain from birth so that he is causally determined to kill the other agent; in the third case, aspects of the agent's community have effects on his development that causally determine him to kill the other agent; in the fourth case, the agent's circumstances are unremarkable, but he is simply causally determined to develop a nature that will lead him to kill the other agent (Pereboom 2016, pp. 76–79). Importantly, a number of conditions for free will that are popularly specified by compatibilists are posited in this thought experiment – for instance, consistency of first-order desires (desires for something) and second-order desires (desires to desire something) on the part of the murderous agent. Another such condition that it is assumed the murderous agent satisfies is responsiveness to reason; in other words the agent is amenable to changing his behavior in light of rational reflection about his reasons for action. These are the sorts of conditions that some compatibilists argue are all that must be realized to hold agents morally responsible for their actions. Nonetheless, Pereboom (2016) claims that he cannot see a "principled" distinction between any of the four cases, and therefore the ordinarily causally determined agent in case 4 is no more morally responsible for the murder in the "basic desert" sense than is the manipulated agent in case 1, who certainly seems non-responsible. This implies that normal causal determination leaves agents no more morally responsible for their actions than causally manipulated agents.

One ambitious reply to the manipulation argument has been offered by the philosopher Michael McKenna, who has endeavored to exploit the fact that the manipulation argument turns on *intuitions* about whether the murderous agent in the cases is

morally responsible for the acts of killing. McKenna argues that we can just as easily see the manipulation argument backwards, proceeding from case 4 to case 1, and alleges that in doing so the compatibilist conditions of free will, such as the consistency of first- and second-order desires, will figure more prominently in one's mind than the acts of manipulation, and thus one may at least come to reasonably doubt that the agent in case 1 is not morally responsible for the murder (McKenna and Pereboom 2016, pp. 167–168). But one may think it does too much violence to the concept of moral responsibility even to doubt that the agent in case 1 is not responsible for the murder since, after all, the murder flows so directly from the activities of other agents. One might hope that compatibilists could draw a more robust distinction between, on the one hand, cases 1 and 2 and, on the other, cases 3 and 4 that could not be answered by mere revision of the manipulation argument (on the matter of avoiding rebuttal by way of such revision, which McKenna's response explained above aims to do, see McKenna and Pereboom 2016, p. 164).

Libertarianism

Libertarianism about free will comes in three varieties: event-causal, agent-causal, and non-causal – but only the first of the three will be considered here given limitations of space. Event-causal libertarianism is the view that free agents' actions are indeterministically generated in such a way that the actions are "truly up to" (Strawson 1986) the agents but are nonetheless brought about by other actions (or mental "events") of the agent. In the experience of the current author, libertarians less often marshal reasons to believe that libertarianism is true than they merely try to show that libertarianism is possible or coherent. Some libertarians have argued that the phenomenological experience of free will is *prima facie* evidence for the existence of free will, and that in light of this evidence we are justified in believing in free will until we have reasons sufficiently strong to engender doubt or skepticism about the accuracy of this

phenomenology (which free will skeptics would of course claim we *do* have). Event-causal libertarianism specifically faces the problem of plausibly explaining how actions can be indeterministically generated but still within the agent's control, such that performing the actions is really "up to" the agent. It is hard to see how the mental events of agents cause their actions but do not fully determine those actions, in a way that is ultimately outside of the agents' control, or randomly or probabilistically generate them.

Conclusion

The contemporary free will debate most saliently involves diverse responses to the threat of causal determinism. Since all aspects of the debate are characterized by strong, even inveterate, disagreement, there is no consensus on whether or not free will exists.

Infidelity In the context of marriage, sexual activity with a person other than the marriage partner

Introduction

This entry will discuss the frequency of infidelity in the context of marriage, defined as "a socio-sexual and socially recognized bond of some duration" which is typically, but not always, established between a man and a woman

(Weisfeld et al. 2018, p. 5). Typically, marriage has the purpose of raising children in common; this nearly universal arrangement usually brings with it a commitment to sexual exclusivity with regard to one's spouse. In this context, infidelity is then a violation of that commitment to sexual exclusivity by one spouse or the other, by means of sexual involvement with another person outside the marriage. The entry here will not deal with polygamy (the publicly recognized arrangement whereby one may have multiple spouses), or polyamory, defined as the practice of having more than one sexual relationship at the same time, with the full knowledge and consent of all partners involved.

First, a brief review of problems in conducting research will be discussed, followed by some statistics on infidelity. Then a discussion of evolutionary and cultural pressures to increase or decrease infidelity will be presented, followed by results from research on five different cultural groups (Nowak et al. 2014).

Research on Infidelity

It is difficult to conduct research on marital infidelity, for several reasons; furthermore, these challenges make it difficult to compare results from different studies. First, there is the issue of timing of the act(s) of infidelity; one tends to get lower percentages of people answering affirmatively if the question is "Are you currently sexually involved with someone outside your marriage?" as opposed to "Over the course of your marriage, have you ever been sexually involved with someone besides your spouse?" Also, young couples may not have experienced non-marital sex yet but may later on. Second, the meaning of infidelity may not be the same for all respondents; some may see engaging in heavy petting or oral sex with a non-marital partner as being unfaithful, while others insist that only sexual intercourse with a non-marital partner would qualify as sexual activity amounting to infidelity. Thirdly, there are methodological issues; for example, Whisman and Snyder (2007) found that when married women were asked face-to-face

about infidelity, 1.08% answered affirmatively but when asked via online questionnaire, 6.13% of women reported being unfaithful to their spouses. Lastly, there is the issue of cultural taboos regarding infidelity itself and also research on infidelity. For example, in the research in China reported below, there was great resistance to asking the question about infidelity; eventually, a compromise was reached with the Chinese collaborators whereby the question in the survey was written in such a way that respondents could be referring to real or imagined infidelity (Nowak et al. 2014).

Frequency of Infidelity

The first major sex survey in the USA was Alfred Kinsey's research described in his two best-selling but heavily criticized (due to nonrandom sampling) volumes. In the first volume, the research team reported that 50% of men had had sexual relations outside their marriage at least once; in the second volume, they reported that 26% of women had been sexually unfaithful at least once while married. Subsequent research efforts have reported lower numbers. For example, Hunt (1974) reported an incidence of 41% for US men and 18% for women. The National Health and Social Life Survey (NHSLS) conducted interviews with 3432 participants selected randomly from noninstitutionalized US citizens; this research reported that 25% of married men reported ever being unfaithful to their wives, while 10% of women reported ever being unfaithful to their husbands (Laumann et al. 1994). These last numbers are also in line with Greeley's 1994 article, in which he reported 21% of husbands and 11% of wives describing having been unfaithful at some point in the course of their marriage.

Cross-culturally, more societies report that infidelity is moderately common than societies report that it occurs at a very low rate. Broude and Greene (1976) reviewed data on 56 societies and found that virtually all men engaged in extra-marital affairs in 13% of tribal societies, a moderate number in 56%, and relatively few in 31%. Only 23% of 116 societies prohibited male

infidelity, compared with 89% for female infidelity, a testament to the ubiquity of the double standard. Rates of infidelity can also be indirectly estimated by studies investigating non-consanguinity rates for father-child dyads. These rates can be as high as 20% (Geary 2005). Russell and Wells (1987) estimated non-paternity on the basis of relatives' feelings of closeness to various children and concluded that the rate was somewhat higher than the 4% found in an earlier British study. Another indirect indication of the evolutionary prevalence of infidelity is the existence of adaptations in men for sperm competition and for selection of semen from different men in women.

Evolutionary Pressures

Evolutionary pressures have been cited as influences working to increase marital infidelity and to decrease it; the same can be said about cultural inputs. A consistent finding is that men's rates of extramarital sex exceed women's. This is consistent with sexual selection theory. In most species including all mammals, the female makes the greater total parental investment, so a male can gain by securing sexual opportunities that may eventuate in his passing on his genes even with minimal parental effort on his part. Therefore men may increase their fitness through sex outside of marriage at little cost to themselves. Female mammals will inevitably have to invest appreciably in their offspring, and so an ill-considered mate choice is hazardous. In species with paternal investment such as humans, the female will gain greatly by securing some paternal investment, so extra-pair sex whereby such support is uncertain is seldom a viable option.

An unfaithful wife risks incurring the wrath of her husband. However, in theory a wife might increase her fitness by being fertilized by a high-quality male (one with good genes or abundant resources), as long as she does not seriously enrage her husband or he remains ignorant of the affair. Wives sometimes engage in extramarital affairs in the process of moving toward divorce and remarriage. Wives are more likely to be

unfaithful when ovulating, which is when they find masculine men especially attractive, thus supporting the good genes hypothesis. At mid-cycle, men engage in more mate guarding.

Cultural Influences

Cultural forces can vary these considerations. For example, in matrilineal cultures, the mother's brother tends to invest in her children more than her husband does (the avunculate). Marriages tend to have high rates of promiscuity because the wife is less dependent on her husband for assistance and so may choose to risk offending him by being unfaithful.

In cultures in which the wife has her own economic resources and is less dependent on her husband, she may be willing to be unfaithful and risk his deserting her. In cultures and social classes in which husbands contribute relatively little in parental investment, enforcement of norms of female infidelity is more lax.

Cultures in which the father invests substantially in his children may effectively enforce the wife's sexual fidelity by practices such as her sequestration, chaperoning, veiling (to prevent other men from forming amorous attachments to her), and sex segregation.

Some cultures strongly discourage divorce even in cases of infidelity if valuable economic or political alliances are built up between the families of the wife and husband.

Extramarital sex may also take the form of rape, which is more common where there are many unmarried males, as in polygynous cultures. Rape is common in warfare when women are unguarded. Another form of extramarital sex is prostitution, resorted to almost exclusively by husbands rather than wives.

Findings from the MARQ Studies of Five Cultures

The Marriage and Relationship Questionnaire (MARQ) was developed in England as a multi-purpose survey instrument appropriate in various

cultures (Russell and Wells 1993). The MARQ has undergone rigorous invariance testing (Lucas et al. 2008), and its major scales have demonstrated both cultural and gender invariance, thus making the MARQ a reliable instrument for examining predictors of marital satisfaction and dissatisfaction across cultures (Weisfeld et al. 2018).

Nowak et al. (2014) reported on the percentages of husbands and wives who responded affirmatively to the question, “Do you find sexual fulfillment outside your marriage?” Responses were counted as negative if the respondent marked “Not at all” or “Not really.” Affirmative responses were those marked “Some” or “Quite a lot” or “Very much.” (Note that the question asks about the current time, rather than whether an incident of infidelity ever happened over the course of marriage – the latter question would generate higher percentages.) In every country, husbands were one-and-one-half-to-two times as likely to report being unfaithful as compared to wives; each sex difference is statistically significant. Percentages of husbands reporting infidelity were 29.2 (Chinese), 25.2 (Russian), 12.9 (Turkish), 9.3 (American), and 6 (British). Percentages of wives reporting infidelity were 19.8 (Chinese), 14.3 (Russian), 6 (American), 5.9 (Turkish), and 4.3 (British). A quarter of the Turkish marriages were arranged, as opposed to being self-selected, and the frequency of sexual fulfillment outside the marriage was not significantly different in those two groups. These cultural groups were combined to examine predictors of infidelity via regression analyses, and those results are reported in the 2014 paper (Nowak et al.). Also, as the paper points out, with regard to the American sample, “The infidelity sex ratio of the comparable Laumann cohort (1963–1974), 1.58, was very similar to that of our own US sample, 1.56.”

The MARQ data require qualification regarding cultural differences in frequency of marital infidelity. The infidelity rates in China were high partly because so many couples lived in different cities and also because of the discreet wording of the questionnaire item, mentioned above. The Russian rates were high in part because of

the difficulty for estranged couples to find housing in order to divorce and live apart.

Conclusion

In general, infidelity is more likely if love and sexual satisfaction within marriage are low and if the spouse is unfaithful. Less attractive spouses guard their mates more than do more attractive ones. More attractive spouses are guarded more closely than less attractive ones.

Frequency-Dependent Selection

Peter Takacs

Negative frequency-dependent selection; Positive frequency-dependent selection

Definition

Frequency-dependent selection occurs when the fitness of a phenotype, genotype, or allele varies with its relative abundance in the population.

Introduction

Frequency-dependent selection occurs when the differential survival and reproduction of organisms in a population depends on the trait (allelic, genotypic, or phenotypic) frequencies of other conspecifics in the same population. It is common in nature and perhaps even the norm for most biological systems (Dieckmann and Ferriere

2004). Traits that affect mating success, resource competition, and predation, for example, often generate situations where the relative fitness of a trait variant depends on its frequency in the population. Despite its ubiquity, frequency-dependent selection is too often neglected when reasoning about selective processes.

Types of Frequency-Dependent Selection

There are two basic varieties of frequency-dependent selection: *negative* frequency-dependent selection and *positive* frequency-dependent selection.

Negative frequency-dependent selection has clearly garnered the lion's share of attention in evolutionary population biology. It occurs whenever the fitness of a trait decreases as its frequency relative to competing trait variants in a population becomes greater. Put simply, becoming more common makes a trait, along with the organisms that bear it, less fit.

Undoubtedly, the most celebrated example of negative frequency-dependent selection comes from the work of Carl Düsing and subsequent articulation by Ronald A. Fisher, after whom it has come to be called “Fisher's Principle” (Fisher 1930; Edwards 1998). It has been shown that, for any out-breeding sexual species, the probability of an individual being able to breed depends on the frequency of its own sex in relation to the opposite sex. The explanation of equal sex ratio begins by assuming that the reproductive cost of producing a female is equal to that of producing a male and, then, stipulating a biologically realistic scenario in which excess females are born to the parents (P) of first-generation offspring. In such circumstances, any first-generation offspring (F1) of the male sex would have better mating prospects on average than any first-generation offspring of the female sex. Consequently, a first-generation (F1) male tends to contribute more offspring on average to the subsequent second-generation (F2) than its female counterpart. Now, from the perspective of the original parental generation (P), any genetic disposition to produce more male offspring will

have been favored by natural selection as it yields more average grandoffspring (F₂). Genes for producing male offspring are accordingly expected to spread in the population until the sex ratio reaches 1:1 (50% male, 50% female). At that point, however, the selective advantage which accrued to genes for producing male offspring ceases since males no longer have better mating prospects than females of the same generation. The sexes then have equal relative fitness. Furthermore, capacities that produce females will be at a selective advantage whenever there are excess numbers of male offspring. Whereas the male phenotype and any genetic mechanisms which bias gamete formation in its direction were favored in circumstances of excess female production, exactly the opposite holds true when there are excess numbers of male offspring. There is thus a pendulum-like frequency change in evolutionary dynamics which stabilizes around the equilibrium sex ratio of 1:1 and ultimately explains why a sex-determination mechanism yields equal proportions.

Examples of negative frequency-dependent selection abound. Within biological game theory, which focuses exclusively on phenotypic traits (or strategies) and the optimal outcomes (or payoff states) of episodic natural selection, an organism playing an aggressive or confrontational strategy known as “hawk” will flourish in a population comprised primarily of passive players known as “doves.” However, a dove will tend to do better in a population composed mainly of hawks (Maynard Smith 1982). It has recently been shown (Kokko et al. 2014) that the head-color polymorphism of red and black Gouldian finches (*Erythrura gouldiae*) strongly supports the game-theoretical model for limited aggression in an animal population. The aggressive red morph is behaviorally dominant and successfully invades black populations, but when red “hawks” become too common, their fitness is severely compromised via decreased parental ability. Other studies indicate negative frequency-dependent selection for self-sterility alleles in plants, handedness in the feeding morphology for scale-eating cichlid fish, and male reproductive strategies in a marine isopod (Stevens 2011).

For a human example, we need to look no farther than studies of host-pathogen coevolution. The African sleeping sickness parasite (*Trypanosoma brucei*) sequentially changes surface antigens as hosts develop antibodies. Host antibodies tend to target the most common antigens, and negative frequency-dependent selection preserves genetic diversity of parasite antigens as well as genetic diversity of the antibodies in their hosts (Stevens 2011). Overdominance or heterozygote advantage presents yet another interesting example in this area. Overdominance occurs when the heterozygous genotype is selected over either of the homozygous genotypes. The classic case involves sickle-cell disorder in malaria-ridden regions. There is a frequency-dependent component in this case because rare (deleterious recessive) alleles are disproportionately found in heterozygous genotypes, whereas common alleles are disproportionately found in homozygous genotypes. So rare alleles always appear to have an advantage.

Positive frequency-dependent selection often goes unmentioned alongside its more oft-cited counterpart. It is, nevertheless, no less important to evolutionary dynamics. Positive frequency dependence occurs when the fitness of a trait variant increases as its frequency relative to competing trait variants in a population becomes greater. In other words, becoming more common makes a trait type, along with the organisms that bear it, more fit.

Perhaps, the most uncontentious example of positive frequency dependence is that of Müllerian mimicry (Müller 1879). Consider, for example, viceroy and monarch butterflies. Both species share an honest color indication of their unprofitability (noxious taste) to predators in the form of bright orange wing coloration and pattern. It is likely the case that predators (e.g., birds) must kill a certain number of individual butterflies with a certain signal before they learn to avoid it. When predators must learn to avoid only one signal instead of two or more distinct signals, it decreases any individual butterfly's risk of being killed. By sharing an honest warning signal, then co-mimic species can benefit from the shared mortality costs of educating the predators to

avoid that signal. An increase in the number of any of the co-mimics should benefit all, as the more individuals there are that share the honest signal, the lower the per capita predation risk. Consequently, rare signal variants that are not genuinely distasteful or simply much less distasteful to predators should be at a disadvantage (Ihalainen et al. 2008).

The Importance of Positive and Negative Frequency-Dependent Selection

Frequency-dependent selection is apparently widespread in many natural populations. While the extent of its scope is a somewhat recent discovery, the phenomenon of frequency-dependent selection has been entertained since the work of Charles Darwin. Why, then, is so much current research focused on elucidating frequency-dependent selection?

Answering this question requires briefly revisiting the general features of natural selection. As resources are limited, there will be heightened intraspecific competition among individuals within a population who bear distinctive heritable trait variants. Insofar as these trait variants differentially affect the average probability of survival and reproduction for the individuals that bear them, the frequency of such traits will systematically change across generations. Trait variants that increase relative fitness tend to become more common or even go to fixation, while less fit variants correspondingly decrease or possibly disappear. This is the (oversimplified) microevolutionary basis for adaptation and ultimately the macroevolutionary phenomenon of speciation. Note that the role of natural selection is primarily one of culling existing variation and, thereby, continually adapting populations to deal with local environmental challenges to survival. The explanatory problem is that most populations exhibit abundant genotypic and phenotypic variation which cannot alone be explained by observed rates of mutation or migration.

It is precisely at this point where the appeal of negative frequency-dependent selection becomes clear. Because becoming more common reduces

the fitness of a trait variant, rare trait variants can be maintained. Here is an explicit way to maintain genetic and phenotypic variation in a population that does not rely on reference to a spatially or temporally variable environmental. Negative frequency-dependent selection is thus typically considered a form of “balancing selection” in that it explains the preservation of variation and extends the possibility of evolutionary rescue.

Positive frequency-dependent selection, in contrast, amplifies the effects of directional selection. Other things being equal, directional selection in finite populations will increase the relative frequency of the fittest trait variants and eventually drive them to fixation if unencumbered. Positive frequency dependence simply accelerates this process since it increases the relative fitness of a common trait variant as its relative frequency increases. There will correspondingly be ever stronger selection against rare variants as they become scarcer. This can obviously have dramatic consequences regarding the rates of adaptive evolutionary change.

Conclusion: The Conceptual Challenge of Frequency-Dependent Selection

Frequency-dependent selection makes fitness values depend on a constantly evolving trait distribution in a population. As such, an individual cannot reliably transmit its fitness to its offspring even when it has the capacity to transmit its traits with perfect fidelity. But if fitness is not stable across generations because of frequency dependence, then mean fitness in a population will not necessarily increase. Gene frequencies might just cycle indefinitely without ever attaining equilibrium (Rice 2004, p. 14). This is a bleak outcome, for it threatens to sever the intuitive explanatory link between natural selection and adaptation.

Responses to this rather dire possibility have fallen largely into two camps. In order to preserve the causal and explanatory connections between natural selection and adaptation, some contend that individual fitness can be maximized despite the apparent problem posed by frequency dependence. Notable among those who are so inclined is

the theoretician Alan Grafen, who has dubbed his approach the “Formal Darwinism Project” (Grafen 2009). An altogether different response can be found in a research program that is based on the mathematical framework known as “adaptive dynamics” or “evolutionary invasion analysis” (Geritz et al. 1998). This approach arose in the early 1990s largely in response to the conceptual difficulties posed by frequency-dependent selection. It extends evolutionary game theory to account for more realistic ecological dynamics, and it can incorporate both frequency- and density-dependent selection. Only time will tell whether either of these responses suffices to meet the challenges posed by frequency-dependent selection.

Freud's emphasis on sexuality in his explanations of human psychology.

Introduction

In the popular imagination, even among those who are otherwise almost entirely unfamiliar with his work, most people who have heard of Freud at all surely associate him with the notion that sex motivates all human activity. Though a bit of a cliché, this belief is in fact quite accurate, to a degree that even many of the professors who talk about his work (mostly in history of psychology classes, these days) may fail to fully appreciate.

Sex as the Foundation of All Neurosis

Freud always saw himself, throughout his career, as a biological scientist with firm scientific roots, and most of his theory is built on a foundation of inherited, evolved instincts and drives that are required to insure survival. What made him unique among late-nineteenth and early-twentieth century thinkers was simply that he placed greater emphasis on the sex drive than on such things as hunger and thirst and did so in a remarkably transparent manner.

In 1909, 10 years after the publication of *The Interpretation of Dreams*, his most successful book, the then-53-year-old Freud was invited to deliver a series of lectures and receive an honorary degree as part of the twentieth anniversary celebration of Clark University in Worcester, MA. On what would turn out to be the only visit he ever made to the United States, Freud took the opportunity to introduce his core ideas to the American audience in a very straightforward series of lectures, published the following year in the flagship journal of the American Psychological Association. These lectures are a vital source of information on Freud's attitudes in middle age toward his own ideas, and he devotes a considerable portion of the fourth lecture both to the role of sexuality in his theory and to how that has been received by other psychologists:

Even those investigators who gladly follow my psychological labors, are inclined to think that I overestimate the etiological share of the sexual moments. They ask me why other mental excitations should not lead to the phenomena of repression and surrogate-creation which I have described. I can give them this answer; that I do not know why they should not do this. . .but experience shows that they do not possess such a significance, and that they merely support the effect of the sexual moments, without being able to supplant them. (Freud 1910, p. 206)

To the objection that other doctors do not find that their patients report experiences that support Freud's ideas, he responds in the same lecture:

Men are not candid in sexual matters. They do not show their sexuality freely, but they wear a thick overcoat—a fabric of lies—to conceal it, as though it were bad weather in the world of sex. And they are not wrong; sun and wind are not favorable in our civilized society to any demonstration of sex life. . . . But when your patients see that in your treatment they may disregard the conventional restraints, they lay aside this veil of lies, and then only you are in a position to formulate a judgment on the question in dispute. (Freud 1910, p. 206–207)

The most scandalous thing about Freud's perspective, ultimately, was not his emphasis on sexuality, but rather his insistence that it was a fundamental drive for all humans, regardless of age or apparent innocence:

Is there an infantile sexuality? you will ask. Is childhood not rather that period of life which is distinguished by the lack of the sexual impulse? No, gentlemen, it is not at all true that the sexual impulse enters into the child at puberty, as the devils in the gospel entered into the swine. *The child has his sexual impulses and activities from the beginning, he brings them with him into the world* [italics mine], and from these the so-called normal sexuality of adults emerges by a significant development through manifold stages. (Freud 1910, p. 207).

Based on this understanding of sexuality as a fundamental, inborn element of human nature, Freud made those stages the centerpiece of his description of development from infancy to adulthood.

Infantile Sexuality

Freud described the fundamental sexual drive as a quest for sensual pleasure and described his stages of psychosexual development as a progression

through different ways of satisfying that search. During the first stage, the *oral* stage, lasting from birth to around age 2, the child derives pleasure primarily from the mouth, beginning with the acquisition of nourishment from the mother's breast, and thus explores all unfamiliar objects by placing them there first. For approximately the next 2 years, which coincide with the child's acquisition of bowel control and the onset of toilet training, the child is in the *anal* stage, in which the child derives pleasure from controlling the actions of the anus.

The third stage, the *phallic* stage, is perhaps the best known, as it is so intimately connected with two of Freud's most familiar, and most controversial, ideas. During this stage, the focus of sensual pleasure, at least for boys, becomes the penis, which little boys often spend a lot of time touching. Freud's explanation for what girls are focused on during this time also concerns the penis, specifically the girl's realization that she doesn't have one and the resentment this brings. While boys are experiencing sensual pleasure, girls are experiencing *penis envy*.

The really big idea contained in Freud's phallic stage, however, is the *Oedipus complex*, named after the Greek protagonist Oedipus, who inadvertently kills his father and marries his mother. During the phallic stage, boys go through a period in which they bond strongly with their mothers and show less interest in their fathers. According to Freud, on an unconscious level, the boys fantasize about growing up and marrying their mothers. Recognizing his powerlessness against his father, *who might take away the penis if he finds out*, the boy resolves this conflict by identifying strongly with the father instead of competing with him for mother's affection. The same mechanism occurs in reverse for little girls, who fantasize similarly about marrying their fathers and resolve the conflict by identifying with their mothers. Freud saw incomplete resolution of the Oedipus complex as central to all subsequent mental illness, saying that it "represents the *nuclear complex* of every neurosis (Freud 1910, p. 212)" and that mental life cannot be understood without it.

The phallic stage, with all its implications for later mental health, is followed by the *latency* stage, a period, from roughly 6 to 12 years of

age, where the child concentrates on schoolwork and sexual impulses seemingly lie dormant. This dormancy ends with the onset of puberty and the start of the *genital* stage, in which sexual pleasure is sought in the company of others, a stage which carries the child into adulthood and beyond.

Conclusion

In a world in which men's descriptions of their own sexuality wore a thick overcoat of lies, Freud's emphasis on sexuality as the primary source of our unconscious motivations, even in early childhood, was so startling that it remains controversial over a century later. Although scientific research has tended not to support his ideas, and modern scientific psychology has largely distanced itself from his influence, his ideas undeniably remain quite well known, and quite influential, in our new century.

Sigmund Freud's (1856–1939) revolutionary, unique approach to understanding the human mind and personality, emphasizing the role of unconscious conflicts and motivations in determining human behavior.

Introduction

While its scientific utility (or indeed, its status as a scientific theory) remains a subject of much controversy, there can be no doubt that Sigmund Freud's (1856–1939) psychoanalytic theory has had as great an impact, both within psychology and in the larger world of medicine and popular culture, as the work of any other thinker before or since. Where Kepler changed humanity's view of itself by taking away our location at the center of the universe, and Darwin changed it again by taking away our unique status as the obvious pinnacle of biological development, separate from and above the animals, Freud changed our self-regard once more by removing much of our self-awareness, arguing that much of what motivates us internally is unconscious and inaccessible to direct observation.

In Freud's model of the human personality, there are three essential components that determine, via their interactions with each other, how people think and behave: id, ego, and superego. The id and the superego belong entirely to the realm of the unconscious mind, whereas the ego represents the conscious part of the psyche, the part of the self of which we are aware and which we willingly show to others. Of these three elements, only the id is already present at birth. The ego begins to develop during infancy and early childhood, and the superego appears some time later. To illustrate the importance of the unconscious components in determining behavior, Freud favored the metaphor of an iceberg to describe the structure of the human mind: when an iceberg is floating in the sea, only about 10% of it is visible above the water's surface, with the remaining 90% unseen beneath the surface. So it is with the

psyche: the vast majority of it is hidden from view, even to its possessor.

The Id

The only component of the personality that is present at birth, the id comprises, in Freud's own words, "... everything that is inherited, that is present at birth, that is laid down in the constitution: above all, the instincts" (Freud 1938/1973, p. 2). The infant, without reason or restraint, is filled with inborn, instinctive needs demanding fulfillment. According to Freud, these unfulfilled needs cause libidinal energy within the id to build up, creating a pressure that demands release, a release that is experienced by the infant as pleasure. Conversely, the postponement or prevention of release is experienced as pain. The infant, possessing no ability to delay release, demands immediate gratification. The id is driven solely by the goal of experiencing as much enjoyment and avoiding as much pain as possible and is therefore said to operate according to the *pleasure principle*.

The id completely controls the newborn, demanding immediate gratification of its needs for food, drink, sensual pleasure, and affection. The infant has neither learned nor experienced adult rules or social conventions; thus the id is quite irrational, demanding that its needs be met without regard for present circumstances. This is obvious to anyone who has ever handled a hungry infant but been unable to feed him or her right away: there can be no reasoning with the newborn, no making of excuses. Delays in gratification are met only with increased anger and agitation. According to Freud, the baby's awareness is, at first, limited to two things: discomfort, created by unfulfilled needs that demand attention, and pleasure and relief when those needs are satisfied. As the child has not yet developed any sense of differentiation or boundaries between self and other, his/her own needs form the whole of the universe.

Over time, the infant begins to develop an increasing awareness of its surroundings, along with a slowly growing sense of the distinction

between those surroundings and the self. Whenever an infant feels hungry and cries, somebody will eventually feed the infant, thus reducing the tension of hunger and producing the feeling of pleasure. Over many iterations of this cycle, the baby's memory will eventually store a representation of both the food and the feeder, via their taste, smell, sight, sound, and feel. Non-psychoanalytic psychologists would describe the process differently, but all would recognize the result: the baby can now bring to mind the objects that will provide a particular kind of satisfaction (in the present case, food), in response to a particular way of releasing libidinal energy (in the present case, crying).

It is important to note that the id's lack of reason is inevitably accompanied by complete amorality. With no internalized notion of social conventions regarding right and wrong (this will develop later), the id is purely hedonistic. What brings pain and discomfort is always wrong, and what gives pleasure is unequivocally right. If the psyche were to simply stop developing with the id, a person would clearly not get far in life. Fortunately, another component will soon develop that functions, at least in part, to keep us alive and out of jail. This second component, *the ego*, recognizes the limits and requirements of the environment, while also being aware of the demands of the id, and is tasked with finding morally acceptable ways of relieving the pressure of libido, or instinctual energy.

The Ego

Of the three major components of the personality, it is the ego that actually interacts consciously with the world. Its task is to help the id to delay gratification until its needs can be met in ways that do not violate the rules and conventions of society, rules of which the id remains unaware. The ego, according to Freud, develops directly out of the id and is actually a part of the id that has been modified by external influences, thanks to its conscious awareness of that outside world. The id, meanwhile, remains unconscious and unaware and as irrational and hedonistic as ever.

One way of conceiving of the ego's function is as a referee, or mediator, constantly negotiating the conflicts that inevitably arise between the id's (often unreasonable) demands and the reality of the requirements of the social and physical environments. This is difficult, as it requires delaying gratification for an entity that exists entirely below the threshold of consciousness and lacks any awareness of the real world. Unlike the id, however, the ego is conscious and quite aware of the restrictions of the environment. The ego is therefore responsible for providing the child with an initial recognition of the rules and customs of his or her society, as well as an understanding of the penalties that may accompany violations of those regulations.

Whereas the id, which knows only the pursuit of pleasure and the avoidance of pain, operates according to the *pleasure principle*, the ego, with its awareness of the real social and physical environments, operates according to the *reality principle*. Unlike the id, the ego is able to recognize that simply satisfying the drives, especially the sexual and aggressive drives, in ways that are socially inappropriate, is ultimately detrimental to one's chances of survival, whereas observing society's rules and releasing that energy in more acceptable ways will ultimately result in greater satisfaction and less pain.

The Superego

In Freudian theory, there are no innate, inborn moral principles; there is no natural moral law. Morality is a social construction, which must somehow be learned by infants who, as previously noted, are amoral pleasure-seekers, with no sense of right or wrong at all. Newborns do, however, possess the capacity to gradually internalize the values they are exposed to, and which are imposed on them, both by their environment and by the people in it. Infants also arrive equipped with emotional reactions that can be evoked by violating the rules as well as by following them. Acting in a way consistent with our values results in feelings of pride and contentment, whereas acting in opposition to our values results in guilt, shame,

and fear of punishment. These internalized values become the superego, which emerges from the ego just as the ego develops out of the id.

The superego's job is to internalize the monitoring that has previously been performed by adults in the external world: it observes the ego, gives it orders, judges it, and threatens it with punishments, exactly like the parents and others whose place it has taken. Contrary to a frequent popular presentation of Freudian theory, it is not entirely correct to equate the superego with the conscience, which is actually one of its two components: the conscience and the *ego ideal*. The conscience is an internal listing of the prohibitions of the child's society, the actions that will result in punishment (the should *nots*). By contrast, the ego ideal represents positive moral values (the *shoulds*). Very young children, controlled by the id, must be consistently punished for violations and rewarded for good behavior, whereas older children and adolescents often do not require outside consequences, either positive or negative. As they have internalized values as their own, both punishment and approval now also emerge from within. When they violate the rules, they feel remorse and shame, courtesy of the conscience. When they adhere to their values, doing what is right and good, the ego ideal provides praise, pride, and general good feelings.

With all three components in place, the psychoanalytic structure of personality is now complete, and the ego's job has just become harder. In older children, adolescents, and adults, the choice of how to behave now requires the ego to act as a sort of referee among three conflicting sets of demands. The id, irrational as ever, continues to demand immediate gratification, while the ego must also contend with present circumstances in the environment, which often determine the conditions under which wishes can actually be satisfied and which are often beyond the individual's control. While dealing with those demands, the ego must also satisfy the superego, which is frankly just as irrational in its demands as the id. Just as the id demands gratification with no regard for practical or moral considerations, so the superego demands inflexible adherence to the rules, with no allowances made for present

circumstances or the strength of the id's requirements. Imagine, for example, a situation in which a person is on the verge of starvation, and the only way to access food requires stealing it. The id, of course, insists, with no regard for the law, that the food be taken immediately! The superego, with equally small regard for practical considerations such as imminent starvation, vehemently insists that stealing is always wrong, without exceptions! The ego's job is to take both sets of demands into consideration, along with the circumstances of the actual situation, and choose a course of action. There is no course of action that will serve to satisfy both the id and the superego, however, and so whatever action is taken, the result will inevitably include some internal conflict, much of which, like the id and superego themselves, will remain unconscious.

Defense Mechanisms

It is inevitable that circumstances will arise in which resolving the inner conflict in ways that produce no guilt, shame, or other inner trouble will simply not be possible, resulting in anxiety. For these situations, the ego has a specialized set of tools intended to minimize the anxiety resulting from internal conflict.

Freud called these techniques ego defense mechanisms, often shortened simply to defense mechanisms. These are strategies taken to reduce anxiety when more rational approaches to resolving a problem have failed. What all defense mechanisms have in common is that they occur automatically and unconsciously, and when not used to excess, their implementation is normal and even psychologically healthy.

The core idea of psychoanalytic theory is that failure to resolve inner conflicts effectively is the source of psychological problems in general, so it is important that the ego has tools available to prevent anxiety from getting out of hand. Here are some of the better-known defense mechanisms:

Repression: Freud described repression as "deliberate forgetting." In repression, thoughts and feelings that arouse anxiety are simply

banished from consciousness. Freud once drew an analogy to a disruptive audience member in an otherwise polite lecture audience. As such a person would make it impossible to continue the lecture, he would be forcibly removed from the lecture hall and the door locked behind him. He is therefore repressed, but he may make an even greater fuss once he's outside, yelling and banging on the door. Freud's point is that anxiety-provoking thoughts and memories are never completely repressed, and they can only be made to stop disrupting the ego by being allowed back in (during psychoanalysis), thus stripping them of their disruptive power. Repression is a basic mechanism underlying the other defense mechanisms, as they all serve the purpose of protecting the mind from unwelcome thoughts and impulses. The idea of repression has had a great, and often negative, influence in more recent times as the source of Western society's widespread belief in buried memories of trauma, despite an absence of evidence for the existence of such repressed memories.

Regression: A person handles anxiety or conflict by retreating to an earlier, more infantile state of development, as when a child reverts to thumb-sucking during the first few days of school. Freud explained regression as a retreat from unsatisfying reality into an earlier phase of sexual development in which satisfaction was more easily obtained, as well as a return to more primitive forms of self-expression, as when an adult reacts to overwhelming stress by throwing a childlike tantrum.

Reaction formation: The ego (unconsciously) makes uncomfortable or unacceptable impulse look like their opposites. The classic example is seen on school playgrounds, where information that one is liked by another child, especially a child of the opposite sex, is often greeted by exaggerated revulsion. More formally, since instincts and drives can be arranged as pairs of opposing tendencies (life/death, dominance/submission, love/hate, etc.), the ego may handle anxiety-arousing emotions and impulses by facilitating the expression of their opposites.

Reaction formation is in danger of becoming a sort of all-purpose explanatory mechanism, which has been used to explain everything from

homophobia (as a reaction to internal, hidden homosexual tendencies) to Stockholm syndrome (fear of captors is so overwhelming that hostages come to love them instead). The danger of relying too heavily on reaction formation as an explanation of behavior, of course, is that any behavior at all can be represented as actually revealing its opposite: a very kind person is actually hiding sadistic tendencies, the charity worker is actually a misanthrope, and so forth.

Projection: The individual sees his or her fault very clearly in someone else. More formally, threatening, anxiety-provoking impulses are disguised from the self by being attributed to others, as in the case where the married man deals with his own adulterous impulses by becoming convinced that his wife is cheating. Projection especially appears to be a key mechanism in racism, in which impulses or wishes the individual finds completely unacceptable, shameful, or dangerous are attributed to members of another group to which he or she does not belong, where they can then be identified and condemned. Freud, who had many encounters with anti-Semitism as a Jewish scientist in Austria, saw projection as central to that sentiment and as a central reason why the racist so often sees criminality and sexual immorality in other races but not in his own.

Rationalization: Rationalizations are self-justifying explanations for decisions, actions, or beliefs, generated to replace and conceal the actual path by which the person arrived there. Like all defense mechanisms, this process occurs unconsciously to protect the ego from the real reasons for its actions, as when the habitual heavy drinker says that he or she drinks just to be sociable. Rationalization is frequently accompanied by denial, allowing a person to ignore evidence that a particular impulse or habit is harmful by focusing on other information instead, as when a daily cigar smoker insists that his habit is actually healthy, because George Burns smoked them daily and lived to the age of 100.

Denial: When a person is faced with information that is too shameful, uncomfortable, or unpleasant to accept, one way of handling the tension is to simply reject it outright, sometimes despite overwhelming evidence. Denial is almost

certainly the most widely referenced defense mechanism in American popular culture, partly because of its preeminence in discussions of addiction: the first step in 12-step programs frequently consists of admitting that the problem exists. Elisabeth Kübler-Ross also spread the idea widely, making denial the first of her five steps in the confrontation of one's own impending death. Overuse of denial as an explanatory mechanism can lead to unfalsifiable (and therefore useless) hypotheses about other people: anything the subject of the hypothesis says or does that seems to disprove the hypothesis can be interpreted as the subject being in denial, rather than the hypothesis being wrong.

Displacement: Aggressive impulses toward a person who is an unacceptable target for those feelings, due to unequal status or power, are diverted onto a safer target. A man who is humiliated by his boss cannot express his rage directly, as it would get him fired, so he goes home and yells at his wife instead, for example. The wronged spouse may then yell at a child (and may perhaps, via rationalization, believe she is legitimately punishing the child), who then is rude to a younger sibling, and so on.

Sublimation: The process by which a socially forbidden, shameful, or otherwise unacceptable impulse finds a useful, socially acceptable means of expression, rather than continuing to be repressed. Freud primarily gave examples involving artistic expression, as in his attempt to explain the artistic genius of Leonardo da Vinci as the sublimation of his unacceptable homosexual urges. Sublimation also helps people with powerful aggressive drives, however, who may find expression for those drives in competitive sports such as mixed martial arts and American football.

Stages of Psychosexual Development in Childhood

Possibly the most controversial portion of Freud's theory is his view of personality development in childhood, which he described as proceeding through an orderly, invariant set of five stages, each named for the primary focus of the id's

quest for sensual pleasure during that time. Freud believed that if conflicts that arise in each stage are not resolved in a satisfactory manner, it is possible to become fixated on the particular stage, resulting in an abnormal preoccupation with that stage's source of pleasure later in life. A heavy smoker or gumchewer, for example, might be regarded as fixated at the oral stage, during which the primary focus of sensual pleasure is the mouth. The stages are as follows:

Oral Stage: The first stage comprises approximately the first 2 years of life, during which non-psychoanalytic observers would certainly agree that children do indeed use their mouths to explore new objects and enjoy putting things in their mouths. Freud explained that this occurs in part because the child's first contact with the mother in feeding is via the mouth and argued that the child's bond with the mother is therefore inextricably linked with oral contact. Failure to successfully navigate this stage and begin to forge a separate identity from the mother would result in oral fixation. In terms of the mother's contribution to this, Freud argued that oral fixation might be a result of either insufficient time *or* too much time spent nursing, depending on the individual case.

Anal Stage: According to Freud, during this stage the focus of sensual pleasure shifts to the anus, and subsequent personality development will be directly impacted by how parents handle the task of toilet training. Between ages 2 and 4, the child gains control over his or her bowels, making the act of defecation one of the very few things the child can control in an environment that is almost entirely determined by the whims and preferences of adults. If toilet training is started too soon, this will intensify the child-caretaker conflict. Increased conflict can also arise as a result of delaying the start of training for too long, however. If toilet training is experienced as too frustrating *or* as excessively gratifying, this can also increase conflict, along with the possibility of fixation at the anal stage. Parents who are too strict, are too punitive, or lack sufficient patience may produce a problem, but parents whose approach to toilet training is too lax and permissive may cause trouble as well. The result of such conflict may be that the child learns to

control his or her environment through excessive retention or expulsiveness. The anal-retentive person learned as a child to exercise control and get what he wants by refusing to excrete; as an adult he is excessively concerned with neatness and organization, controlling his environment by keeping everything in its place. The anal-expulsive type may have instead controlled his parents by excreting freely and liberally and as an adult may attempt to control others through sloppiness.

The powerful influence of Freud's description of childhood is well-illustrated by the widespread use for much of the twentieth century of the term anal-retentive personality, or simply anal character, to refer to a subclinical form of what is today known as obsessive-compulsive disorder. The anal-retentive character does not come up often in conversation among psychologists and psychiatrists these days, but the idea has certainly penetrated deep into American popular culture. References to such a personality are still readily found, though often the term is shortened and people are simply referred to as "anal."

Phallic Stage: As the stage name suggests, this is the period, roughly from 4 to 6 years old, during which a boy's id shifts the focus of pleasure to the penis. As with the oral stage, the evidence that boys go through something like this is easily obtained; getting little boys to understand that they mustn't sit with their hands in their pants is a major concern in preschools and day-care centers or on outings to public places in general. Given this remarkably male-centric description, Freud would point out that girls are also concerned with penises during this stage, specifically with the question of why they *don't* have one. Observing that boys have penises and girls do not, a little girl may wish that she did and suspect deep down that she had one at one time and that it was removed. Freud called this *penis envy*. During this stage, some boys also fear that they may lose theirs as a punishment; Freud called this *castration anxiety*.

This is also the stage in which Freud suggested the existence of the Oedipal conflict or complex, named after the Greek protagonist Oedipus, who inadvertently kills his father and marries his

mother. During the phallic stage, boys go through a period in which they bond strongly with their mothers and show less interest in their fathers. According to Freud, this occurs partly because on an unconscious level, the boys fantasize about growing up and marrying their mothers. Only one thing stands in the way: dad, who is large and frightening. Recognizing his powerlessness against his father, *who might take away the penis if he finds out*, the boy resolves this conflict by identifying strongly with the father instead of competing with him for mother's affection. When the same essential conflict occurs in girls (substitute father for mother in the preceding text), psychoanalysts call it the Electra complex.

Freud, like much of the psychiatric community until the early 1970s, regarded homosexuality as a disorder to be diagnosed and treated, and he saw its etiology as a failure to properly resolve the Oedipal conflict. Freud argued that boys who failed to successfully navigate and resolve this conflict would remain too strongly attached to their mothers, trying to emulate them rather than their fathers, and would thus grow up homosexual. A similar pattern occurs for girls; psychoanalysis viewed lesbians as women who identified too strongly with the male role model rather than bonding properly with their mothers.

Freud saw the Oedipus complex as the most important event in all of childhood, describing it as "the nuclear complex of all neurosis." In other words, he saw all psychological difficulties, anxiety, and maladjustment in general as originating in this brief period of childhood. All subsequent difficulties have their origin in how the ego handles this unconscious struggle over forbidden sexual desires and the irrational fears that arise from this struggle.

Latency Period: This period follows the phallic stage with several years of concentration on schoolwork until sensual concerns blossom again with the coming of adolescence. It is as though the id has temporarily halted the search for physical pleasure.

Genital Stage: This period begins with the onset of puberty, when the id turns its attention outward in the direction of contact with others, usually of the opposite sex. The genital stage, as

the final stage in the sequence, also describes adulthood.

The Most Direct Path to the Unconscious Mind: Dreams

As the various desires, wishes, and conflicts roiling the unconscious mind are, by definition, hidden from conscious awareness, Freud needed to find a way to access this content in psychoanalytic therapy. Much of psychoanalytic practice consists of *free association*, in which the patient/client simply expresses everything that crosses his or her mind, but this cannot reveal the things which are *not* crossing that conscious mind. For this kind of access, Freud turned to dreams, which he considered the only direct link, the “royal road,” to the unconscious.

Freud's own self-analysis focused heavily on dreams, and before long he decided to write a book about the role of dreams in resolving unconscious conflicts. First printed in 1899.

The Interpretation of Dreams is widely regarded as Sigmund Freud's most important work, and it remains his most widely read book today. The central argument of the book is that the primary function of all dreams is wish fulfillment, including fulfillment of the secret desires which we cannot admit even to ourselves on a conscious level. He further argues that the source of the superficial content of the dream can often be located in the events of the day preceding the dream, which he called the “day residue.” This can appear rather obvious in very young children, because they have very straightforward dreams of the fulfillment of wishes that they were thinking about the previous day. In adults, however, the process of tracking down the source of a dream is rather more complicated, since their dreams, unlike those of the children, have become distorted in order to conceal the underlying wishes. Just as the mind itself has both a conscious and an unconscious component in Freud's model, so every dream functions on two levels, one obvious and one deeply concealed. The surface content, or *manifest content*, is a heavily disguised version of unconscious wishes and desires, which

he called the *latent content*. Understanding the contents of the subject's unconscious mind, which is a primary goal of psychoanalysis, therefore requires correct interpretation of the symbolic meaning of that individual's dreams.

The latent content appears in our dreams because, in Freud's view, many of our unconscious motivations are so unacceptable to us that they create a great deal of intrapsychic conflict between the ego and the unconscious parts of the mind. The only way to alleviate the tension and anxiety resulting from that conflict is to allow the forbidden content to surface, though heavily disguised, in dreams. The disguise is necessary because even in dreams, the individual's resistance to these unacceptable impulses remains too strong to acknowledge them directly. The dream's real significance is completely concealed from the dreamer, and dreamers are unable to grasp the actual meaning of their dreams without the help and guidance of the psychoanalyst. The latent dream content has been transformed by the work of the ego's defenses, operating even while the dreamer sleeps, under the direction of the superego. To Freud, every dream represents some degree of compromise, allowing the disguised fulfillment of repressed wishes while preventing sleep from being interrupted by an impulse so disturbing that it awakens the dreamer.

Based at first on his analysis of his own dreams and later on those of others, Freud believed that certain elements in the manifest content of dreams tend to correspond consistently with certain latent content. Phalluses, for example, are symbolically replaced in manifest content by a wide range of objects that are similar to them in their form, including most long or tall things that jut out in some way; thus a penis can be suggested by mountains, trees, poles, sticks, umbrellas, spires, monoliths, etc. Phallic symbols also encompass virtually anything that has the purpose of penetrating the body and doing harm, including most weapons, such as swords, lances, spears, and guns of all sorts. Freud's list of phallic representations also includes most objects and geographic formations from which water runs or sprays, including pipes, fountains, geysers, crashing waves, garden hoses, and even watering cans. Objects that can be

lengthened can also represent the phallus, including balloons, antennas, springs, and even snakes. The number three is also symbolic of the male genitalia, as well as any dream thoughts that consist of three parts; thus even the appearance of the Trinity in a Christian's dreams may represent the phallus!

Most criticism of Freud's dream symbols tends to focus on the omnipresent phallic symbols, but it is not only male genitalia which are artfully concealed in dreams. In Freud's dream analyses, female genitalia are represented by virtually any hollow object that can contain other objects, including but not limited to bottles, dishes, boxes, bottles, mineshafts, caves, tunnels, pockets, tins, closets, churches, houses, forts, purses, and even landscapes. The phallic snake has female analogues as well: among animals, snails, mussels, clams, scallops, oysters, and the like also represent female genitalia. Meanwhile, fruits such as apples, peaches, pears, and coconuts generally stand in for breasts. Dreams in which playing occurs, whether it be the playing of outdoor games or the playing of musical instruments, are symbolic of masturbation, as are sliding, slipping, or even the breaking of branches. Conversely, a dream that includes a visit to the dentist, or extraction of teeth, is symbolic of *punishment* for masturbation. Many other activities and elements stand in for sexual intercourse itself, including climbing or descending ladders or stairs, traveling on a train, dancing, riding horses, raising a weapon, or running into a house.

Later theorists who embraced the idea of dream interpretation, most notably Carl Jung, tended to place much less emphasis on repressed sexual wishes than Freud did. Though Freud certainly saw other types of anxiety and conflict buried in the latent content of dreams, his focus for the bulk of *The Interpretation of Dreams*, and numerous case studies published in later years, remained primarily on sexual wish fulfillment. Given the fundamental underpinnings of psychoanalysis, this is unsurprising. As noted earlier, he built much of his theory upon the foundational idea that all psychological difficulties originate in the degree to which the individual overcomes, or fails to overcome, the Oedipal conflict in childhood.

Conclusion

While much of Freud's theory has long since dropped out of favor in the scientific psychological community, the fundamental notion that we are frequently not consciously aware of our own motivations, and that those motivations are often sexual, or perhaps repressed memories of long-forgotten trauma, continues to broadly impact popular culture into the twenty-first century. Although his ideas are now seen as pseudoscientific speculation, at best, by most of the scientific community, it is important to note that Freud always saw himself as a biological scientist and that all of the more bizarre elements of his theory grow out of his focus on the role of inherited drives and instincts, as expressed by the id.

Friends with Benefits

Definition

The term “friends with benefits” generally refers to a casual arrangement in which two people have both a friendship and sexual relationship at the same time. Though not romantic in nature, it is possible for romantic interest to precede the arrangement or develop as it unfolds. Friends with benefits have the potential to take various forms depending on the amount of emphasis placed on the friendship versus sexual component of the relationship as well as the motives, goals, and expectations that each partner brings.

Introduction

It has become increasingly common for Americans to report having had sex with someone they consider to be a friend. For instance, General Social Survey data indicates that among college students surveyed in the late 1980s, 56% had engaged in sex with a friend; among students surveyed in 2012, the proportion had increased to 71% (Monto and Carey 2014). The phenomenon of friends who have sex with one another is often referred to in the popular media and scientific literature alike as “friends with benefits” (FWBs).

Research suggests that FWBs can take various forms and that different people define this term in different ways. For example, in a survey of 177 heterosexual college undergraduates who were asked to define “friends with benefits” in

their own words, seven distinct types of FWBs emerged (Mongeau et al. 2013). FWBs appear to vary in terms of the partners’ prior relationship status (e.g., friends, acquaintances, lovers) as well as the motivations and expectations brought to the relationship (e.g., opportunistic sex, romantic interest). That said, the modal FWB appears to be one in which two persons with a preexisting friendship add a sexual component to their relationship. Most FWBs are not sexually exclusive and, though romantic interest is sometimes present at the beginning or develops over time, commitment to these relationships tends to be modest at best (VanderDrift et al. 2012).

Though popular among college students, FWBs are not limited to young adults, nor are they limited to persons of a particular sex or sexual orientation. Research suggests that those who participate in FWB relationships are diverse in terms of their demographic backgrounds (Lehmiller et al. 2011).

Sex Differences in Approaching Friends with Benefits

Heterosexual men and women appear to differ when it comes to their motivations for beginning FWB relationships, as well as their expectations for how these relationships will evolve over time. Lehmiller et al. (2011) surveyed 411 adults who reported current involvement in an FWB relationship and found that men were significantly more likely than women to indicate that sexual gratification was their primary motivation (72% vs. 56%, respectively). By contrast, women were significantly more likely than men to indicate that emotional connection was their primary reason for starting the relationship (37% vs. 25%, respectively). With respect to their plans for the future, most men (60%) reported a desire for the relationship to stay the same, whereas most women (63%) indicated a desire for the relationship to transition into a romance or revert back to a friendship.

One potential way to explain these sex differences is through the lens of evolutionary psychology. Though casual sex can be seen as having adaptive value for men and women alike, men

on average usually stand to gain more than women from casual encounters due to differences in parental investment (Buss and Schmitt 1993). In the context of FWBs, which tend to be sexually nonexclusive (VanderDrift et al. 2012), there is a reproductive advantage offered to men in that these relationships allow them the ability to obtain low-investment sex with more than one partner at a time. From this perspective, it makes sense that men would be more inclined to cite sexual motives for pursuing an FWB and would desire to maintain these open-ended opportunities for casual sex for as long as possible. For women, however, maintaining low-investment, casual relationships with multiple men is riskier because, should they become pregnant, they may lack dedicated resources from the father to support their offspring. Therefore, it makes evolutionary sense that women would be more likely to view FWB opportunities as time-limited or as vehicles for beginning longer-term, higher-investment relationships.

Alternatively, men's and women's reported differences in motivations and expectations for their FWB relationships may be a product of the *sexual double standard*, which refers to the finding that women tend to be judged more harshly than men for engaging in sexually permissive behavior. Given that women are not evaluated as negatively for engaging in casual sex when they are seen as emotionally involved with their partners, it is possible that social pressure may lead women to underreport sexual motives for beginning an FWB and instead emphasize emotional connection.

Outcomes of Friends with Benefits

Given that men and women tend to approach FWBs quite differently and diverge in their expectations for the future, it should come as no surprise that opposite-sex FWBs do not always end well. Further complicating matters is the fact that both sexual and nonsexual communication are lacking in FWBs compared to romantic relationships. Research indicates that most people with FWBs fail to establish ground rules for their relationships

(Bisson and Levine 2009) and that they are less likely than those in romantic relationships to discuss their sexual desires and talk about safer-sex practices (Lehmiller et al. 2014). Part of the reason for these communication deficits may stem from the frequently reported finding that many FWBs only get together when they have been consuming alcohol.

With respect to the outcomes of FWBs, a study of college students who reported FWB experience and who were asked about their relationship status found that 28.3% still had an ongoing FWB relationship, 35.8% were still friends but not having sex, 9.8% had become romantic partners, and 25.9% had no relationship of any kind with their former FWB (Bisson and Levine 2009).

Similar numbers were obtained in a one-year longitudinal study of FWBs, which also revealed that communication was one of the strongest predictors of relationship outcomes (Ioerger et al. 2014). Those who set up ground rules for their relationship at the beginning were more likely to maintain at least some type of relationship with their partner over time. In addition, certain relationship goals were more likely to be achieved than others. Specifically, those whose goal was to maintain a friendship tended to be more successful at doing so than those whose goal was to transition into a romance.

Friends with Benefits and Personality

Research indicates that people with certain personality traits may be more inclined to enter FWB relationships than others. For example, compared to persons in other types of heterosexual relationships, those in cross-sex FWBs tend to have higher levels of attachment avoidance as well as a more unrestricted sociosexual orientation (Greszta et al. 2016). In other words, persons in FWBs are more likely to be uncomfortable with intimacy and have an easier time separating sex from emotion.

Personality is also linked to relationship satisfaction among FWBs (Lehmiller et al. 2016). Specifically, both attachment anxiety (i.e., fear of abandonment) and neuroticism (i.e., emotional

instability) are linked to lower satisfaction. By contrast, erotophilia (i.e., responding positively to sexual cues), sexual sensation seeking (i.e., a desire for thrilling and risky sexual encounters), and an unrestricted sociosexual orientation were related to higher levels of satisfaction.

Conclusions

Casual sex relationships can take many forms, with FWBs being one particularly common – and increasing – variant. Though FWBs are frequently viewed as a monolithic group, research suggests that these relationships vary substantially depending upon the individuals involved and their motivations. This, combined with low levels of communication and differences in men's and women's relationship goals, means that FWBs are often quite complex to navigate and have the potential to result in a range of relationship outcomes.

Friendship and Modern Life

Nick Munn
The University of Waikato, Hamilton,
New Zealand

Synonyms

[Friendship](#)

Definition

Friendships are interpersonal relationships that are voluntary, personal, affective, mutual, and equal.

“Modern life” refers to the set of technologies and means of social interaction that has developed around and with the rise of the Internet. Friendship and modern life is then the set of interpersonal interactions and consequences thereof, which have the features noted above and arise out of relationships between agents as mediated by modern technology and society.

Introduction

The starting point for most modern analyses of friendship is Aristotle. In the *Nicomachean Ethics*, Aristotle describes three kinds of friendship, of which two, the friendships of utility and of pleasure, are imperfect, and the final one, the friendship of virtue, is perfect. In a friendship of virtue, claims Aristotle, each participant wishes well for the other for their own sake, rather than as a means to either the utility or pleasure of the lesser friendships (Ross 1998). According to Aristotle, this perfect friendship is uncommon but has the most capacity to generate the strong positive outcomes that friendships are claimed to produce. This division of friendships remains useful to modern researchers, as the notion of friendships of virtue helps to explain the intuitive dissatisfaction reported by many research participants when it is suggested that friendship between humans can be fully explained by notions such as reciprocal altruism (Tooby and Cosmides 1996).

The distinction between imperfect and perfect friendships in Aristotle is matched by a distinction between “fair-weather friends” and “true friends” in Buss (2016). True friends, on this account, are those who one can trust even when things are bad, and friends of this kind are comparatively rare. This desire for true friends presents us with an adaptive problem, namely, “how to differentiate true friends, who are deeply engaged in your welfare, from fair-weather friends, who will disappear at your hour of greatest need” (Tooby and Cosmides 1996). This problem is compounded by the fact that modern life, as Buss points out, suffers from a relative scarcity of critical events that would allow us to accurately assess those who are

deeply engaged in our welfare and discriminate them from our fair-weather friends (Buss 2016).

As human activity has collectively moved online, the means by which friendships are developed have changed. Until recently, the possibility of developing strong friendships online or in virtual spaces was itself contentious, and at the time of writing this entry, the claim that online friendships differ in kind from offline friendships is a commonplace. Many authors have claimed that true friendships, or friendships of virtue (depending on the academic background of the proponents of the claim), either cannot be established in virtual spaces or online environments or that their development in these domains is significantly more difficult than in more traditional environments. By contrast, it is widely accepted that lesser or imperfect friendships can and do develop in online environments (Cocking and Matthews 2000). This entry examines how modern friendships are created, developed, and maintained and the various issues arising from these methods.

Standard Accounts of Friendship

The five characteristics of friendship outlined by Rawlins that friendships are voluntary, personal, affective, mutual, and equal encompass the core of the notion of friendship (Rawlins 2016). They incorporate notions philosophers have appealed to as being important components of friendship, such as affection and well-wishing (Cocking and Kennett 1998), as well as those of mutual caring, intimacy, and shared activity (Helm 2010). These characteristics are also common in psychological accounts of the type and strength of friendship, which rely on notions of friendship as dyadic and co-constructed, containing elements such as reciprocity, closeness, and intimacy (Amichai-Hamburger et al. 2013). Taken together, these characteristics generate a conception of friendship wherein each friend cares for the other and does so for the sake of the other, not themselves; where the relationship is not one of mere collegiality or acquaintance but is deeper; and where the friends do things together both because they each enjoy

the thing in question and because they enjoy doing this thing in the company of friends (Helm 2010).

The process by which bonds such as those described above develop must however be examined. Friendships do not come into existence containing all these characteristics, and the strength of any of them within a particular friendship can vary dramatically. So, features such as closeness, intimacy, and mutual caring must be developed, and this development requires specific kinds of engagement between friends. Many modes of interaction, including those commonly shared with workmates or casual acquaintances, do not provide meaningful opportunities for shared activity, and participants therefore lack the opportunity to develop these features in those contexts. As Aristotle says, “friendship requires time and familiarity,” and people cannot “admit each other to friendship or be friends till each has been found lovable and been trusted by each” (Ross 1998).

Deep or higher-order friendships provide a range of benefits to those who have them. The development of friendships of this kind enhances the self-knowledge that is necessary for virtue. It provides moral role models for the friends in question, enhances their moral sensibilities, and provides them with objective views of one another (Cocking et al. 2012). If online friendships cannot become deep friendships, and if they replace offline friendships, then the opportunity for these benefits is lost. However, both of these considerations are empirical matters, and there is a growing body of research into how online friendships (and mixed/hybrid friendships) in fact operate. This research is encouraging for those who think that online and hybrid friendships are non-problematic.

Friendship and Modern Life

The modern world has drastically altered how friendships form and develop, and these alterations impact in a range of important ways on how friendships should now be treated. Some of the developments have been gradual, as with the expansion of the ease of travel for the average citizen of a developed nation. From bicycles

through steam travel to cars and cheap international flights, as people’s horizons have expanded, so too have the range of people they can meet and, correspondingly, friends they can make. At the same time, the likelihood that any person will remain in one place has diminished, and so the length and closeness of friendships have been undermined. This combination, of having more potential friends and a lower likelihood of remaining physically close to those friends, puts the status of any particular friendship at more risk than it would have been previously. Framed in Aristotelian terms, the already difficult to establish and build upon friendships of virtue have been getting progressively more difficult. The less valuable, although easier, friendships of pleasure and utility are correspondingly more widespread.

In psychological terms, the worry is that deep friendships offer benefits that shallow (“fair-weather”) friendships do not and that we are increasingly developing shallow friendships at the expense of deep ones, often without realizing that we have done so. Whether this concern is realized depends on the nature of our interactions in online spaces, and the science is not settled on this. Opinion remains deeply divided on whether recent technological developments are helping or hindering the development of friendships. On the one hand, retaining contact with those who one no longer lives near to is made possible by the connected nature of an Internet-enriched world. But on the other hand, the kinds of interactions one has online may not, many claim, be relevantly similar to those we have in the physical world. They may lack something crucial to (or merely helpful for) the development of friendships. Fröding and Peterson, for example, claim that online friendships are of the kind Aristotle would have described as lower order or less valuable (Fröding and Peterson 2012). McFall similarly claims that higher-order Aristotelian friendships cannot occur entirely online (McFall 2012). In these and similar objections, the presumption is that offline friendships are distinct from and superior to online friendships. This claim arises both from the Aristotelian friendship tradition and from psychological research into the strength of different types of

friendship (online, offline, and mixed). There are two features of the research that should be examined. Firstly, there is a worry about the mischaracterization of online friendships, in that friendships within particular online domains are often compared to friendships developed offline. This comparison is biased in favor of offline friendships in ways that diminish the value of online ones, as will be discussed below. Secondly, much of the research focuses on deep or higher-order friendships, at the expense of consideration of the more common kinds of friendship. This focus obscures the value of lower-order friendships, whether online or offline. Before analyzing the concerns shaping each of these approaches, the conceptual space within which the different kinds of friendship operate should be considered. Firstly, there are offline friends. These are friendships developed in the traditional manner, through interaction in the physical world. Secondly, there are online friendships, those developed in virtual spaces and online worlds. Finally, there are mixed-mode friendships, those in which the virtual and the physical world both play roles. Within this last category, the extent to which the offline and online modes of interaction occur varies dramatically.

Three Kinds of Modern Friendship

Until recently, there have been few options other than to establish friendships through the medium of the offline world. Communication with those not physically co-located was slow, expensive, or both when the available options were letter writing, telegrams, or even telephones. However, the advancement of technology and the development of the Internet have removed many of the barriers to communication between distant persons. As such, there are now three clearly distinguishable ways in which friendships can be developed. It remains possible to develop friendships offline, in the physical world. Friendships can be developed online, eschewing physical interaction. Finally, a combination of online and offline interactions can be utilized to develop “mixed-mode” friendships (Antheunis et al. 2012).

It is worth noting that friendship solely mediated in the physical world is rapidly becoming less common, as the reach of online communication tools expands, both in terms of availability and uptake. More and more frequently, friendships that begin purely offline expand into online domains, simply because virtual worlds are becoming ubiquitous. Indeed, it is increasingly uncommon for a friendship not to include online components, as a key part of the development of a friendship is, now, to connect with the friend’s online presence.

Consider a paradigmatic tale of the development of friendships for an individual. The earliest of our friends are those whom we meet and interact with when we are very young. They will be, for example, the children of our parent’s friends, if similar in age to ourselves. Otherwise, they will be our classmates from preschool or the early years of school. As people age and move from school to university, or into the workforce, they will both develop newer friendships and discard some of the old ones. Sometimes this will be intentional, as one party or the other discovers that they lack shared interests with some of their earliest friends or as their interests diverge. At other times, circumstances will separate people from these friends, as when families move away. These friendships, as described, arise solely in the offline world, and they share a common feature, that is, they are discerning. This means simply that individuals do not automatically develop friendships with all those they meet, regardless of the domain in which they meet them. One can have classmates and work colleagues who are not friends. Rather, similarity is important, as similarity enables a deeper and more meaningful connection with others. Further, both parties to a friendship need to enjoy each other’s company for a friendship to prosper. This is a mutuality requirement. Whether this is the case is discovered via engagement in shared activity. By engaging repeatedly in shared activities over time, people develop the bonds of intimacy and mutual caring which characterize deep friendships.

This description relies solely on offline interactions. Yet it is easy to see how online interactions could supplement this story, thereby leading

to an origin story for a mixed-mode friendship. It is perhaps not as easy but still relatively simple to replace the initial offline points of contact with online points of contact and from there to describe the development of a friendship that is purely online. To the extent that our behaviors in the online worlds we inhabit in our modern lives parallel those behaviors we exhibit in the offline world, the case for friendship remains the same. However, there is some reason to believe that a twofold disruption of this similarity is occurring. Firstly, geography and contact have been separated – it is now possible to maintain close connections with those who are not geographically co-located, in ways that were impossible even a generation ago. Secondly, the pace of change is now rapid, such that any status quo regarding friendship formation and maintenance behaviors is unstable. These two factors are a concern for all three kinds of friendship in modern life.

Friendships are valuable things. They influence our moral behaviors, insofar as friendships generate motivations to act toward friends that are not present toward strangers. They enhance our knowledge, in that exposure through the medium of friendship to the lives and experiences of those different from ourselves provides us with insights into these other worlds that we either do not get or do not fully understand, when we are exposed to them in other ways. So, both issues of geography and issues of technological change could seriously impact on our well-being, if these changes disrupt our modes of friendship formation, causing us to have fewer or less beneficial friendships than we previously had. However, the widespread pessimism regarding online interactions seems ill founded. There is a tendency to assume that as online interactions increasingly replace offline ones, important components of socialization are lost. After all, young people are no longer doing the sorts of things their parents did. They eschew offline social gatherings (at least to some degree) in favor of online interactions. But there is value in these online interactions, and at least some of this value is unique to the online space. In spending their social time online, people who develop true friendships in online spaces are making friendship connections with a broader and

different range of persons than are generally available to them through physical world social networks. This is more important than is sometimes recognized, as for those engaging in online activities, there are a significant number of potential friends, from a divergent range of backgrounds, societies, and situations, who would not be available as potential friends absent the online environments which enable contact with them (Munn 2012).

The above considerations are general advantages potentially accruing to those who engage in online social interactions. It is however also very important to note that there are significant advantages to the possibility of developing friendships either purely online or in mixed modes, which accrue to certain people within society. Those who for whatever reason do not conform to societal norms and expectations of behavior are offered greatly expanded opportunities for friendship in online domains. Consider the wheelchair-bound teenager, who will never be able to physically play football with others. An online community allows them to develop friendships with others based on a shared enjoyment of football, and to play football, albeit in digital form, with these others. This is not merely a means of connecting with those who the teenager could have met otherwise – those in the same offline area. It also connects them with people for whom the fact of the particular physical disability is irrelevant. If one has a reasonable expectation that they will never physically meet someone, then a physical restriction such as being wheelchair bound not only does not matter as much but also may be purely irrelevant to the development of the friendship.

It is possible to usefully divide the possible advantages offered by online friendship formation into three kinds: frequency, variety, and opportunity cost. The frequency advantage offered by online friendship formation is simply that we can have many more online friends than offline friends, as interactions with them are able to be faster, more flexible, and easier to accommodate around competing schedules. This results in more opportunities for development of these friendships. The advantage in variety arises from the availability of potential friends online. We have

a wider potential friend base online. There are no geographical constraints, as asynchronous communication renders time zones irrelevant, and the online medium eliminates the need for propinquity (Amichai-Hamburger et al. 2013). This does not mean that physical co-location ceases to play a role in friendship development. Rather, online communication serves an important role in strongly mixed friendships, with social networks being used in large part as a supplementary means of communication between people who are in roughly the same physical location, either within the same state or within the same city (Mazur and Richards 2011).

There is, importantly, a reduced emphasis online on common signals of differential social status, such as age, race, and social class, as well as a reduced emphasis on behavioral cues such as physical attributes and perceived similarity (Chan and Cheng 2004). These things are not as relevant to online friendships (or to mixed-mode friendships, although they retain more relevance in that context). As such, online friendships are distinctly valuable because they provide the opportunity for those that have them to interact with and gain knowledge of people in social settings distinct from their own, more easily than is the case without online friendship. This knowledge could be gained in other ways (as, e.g., when one befriends new arrivals from abroad), but the possibility of real friendship formation online makes such friendships more feasible for more people, more often.

Finally, the nature of online friendships is such that the opportunity cost of developing them is less than is the opportunity cost of developing offline friendships. Buote et al. note this in claiming that online friendships are perceived as less risky and easier to initiate, and that it is easier, in online environments, to present oneself as one wishes to be perceived. The asynchronous nature of communication means that those less confident in expression, or quick of thought, have the time to ensure they say what they mean, in ways that are unavailable in offline interactions (Buote et al. 2009).

Much the same expansion of opportunity has arisen across many domains of human behavior

and in ways that the offline world could not provide. Whether an individual is shy or socially awkward, or has a set of beliefs or values that is not common in their physical community, or any of a variety of other considerations, the online world provides hitherto unfathomable opportunity to discover like-minded individuals and to form relationships with them. These relationships, even if they begin online, will with some frequency become offline friendships as well. Even as far back as 2007, Cole and Griffiths found that it was very common for people to meet online friends in offline environments, with 55% of females and 38% of males reporting having met online friends in “real life” (Cole and Griffiths 2007). This is suggestive of the increasing importance of mixed-mode friendships, those mediated both through offline and online interactions, as not only are offline friendships moving into online spaces as a supplementary means of engagement, but the reverse is true. This is a component of the stimulation hypothesis, which sees the role of online communication as being to enhance existing friendships, thereby developing stronger bonds which improve the friendships (Valkenburg and Peter 2011).

It is at this point that the distinction between fair-weather friends and true friends, or between imperfect and perfect friendships, again becomes relevant. While we clearly can and do develop friendships of some kind online, it is still open to the defender of traditional (offline) friendships to claim that these online friendships are only of the lesser kind; that they are not deep or true friendships, they are imperfect. If this claim holds, then there is reason to be skeptical of online friendships, as there is a value in true friendships that is not present in fair-weather friendships, and something important would be lost if we lost this. However, it is already the case that in order for the claim to be true, it must be that many users of a broad range of online services are themselves mistaken, as they do not think that the quality of friendships offered by the online world is inferior to that offered by the offline world (Amichai-Hamburger et al. 2013).

The Capacity to Develop (True) Friendships

Recall that modern friendship is divisible into three distinct kinds: offline, online, and mixed friendships. Arguments about the capacity to develop these friendships focus on online and mixed friendships, as it is uncontroversial that we are capable of developing friendships in the physical world. We do develop them; therefore, we can develop them. The question for proponents of the possibility of developing either online or mixed-mode friendships is then the following: is there anything to distinguish between purely offline interactions on the one hand and purely online or mixed-mode interactions on the other, when it comes to developing the kinds of bonds that lead to friendships? The currently available evidence suggests that there is not, and that as such, online and mixed-mode friendships can be all that offline friendships are. Indeed, there are particular advantages that online and mixed-mode friendships appear to have over offline friendships, such that they may be in some ways superior. For instance, there is evidence to suggest that whether a particular friendship is same sex or cross sex matters less in online spaces, as sex matters less. Chan and Cheng argue that this is because the structural and normative constraints present offline have not, or not wholly, established themselves online and so are less effective in impeding the development of cross-sex offline friendships (Chan and Cheng 2004). While one can hold to the possibility of a friendship becoming sexual, the triggers for such behavior are diminished online, and the strength of the possibility is diminished also. Chan and Cheng found, for example, that under their methodology, online cross-sex friendships were stronger, or of higher quality, than were online same-sex friendships, while for offline friendships, the reverse was true (Chan and Cheng 2004). This could be because the triggers for certain breakdowns in friendship (such as the attempt on the part of one friend to change the nature of a relationship from companionable to sexual) are less available in online spaces. The Internet is, to some degree

at least, a safe environment for the development of cross-sex friendships, in ways that the offline world is not (Chan and Cheng 2004).

A distinction commonly appealed to in defense of the claim that there is a meaningful difference between offline and online interactions is that, while the offline world enables us to interact with each other and learn about characteristics such as our character and desires with some degree of accuracy, the online world does not. As such, it is claimed that we are able to trust and to make judgments on the validity of claims to friendship in the offline world, but not in the online world. The key feature of this type of argument is a reliance on shared activity: friends do things together, and it is this engagement that lets them develop the strong bonds of friendship. However, shared activity is increasingly possible in online spaces, and it is unclear there is anything special left for the offline domain. Buote, Wood, and Pratt found that online friendships provided equal levels of quality, intimacy, and self-disclosure as did offline friendships and concluded that this was evidence that online friendships were a positive and beneficial alternative to traditional friendships (Buote et al. 2009). Winning a game in your casual football league does not matter any less if the league is virtual than if it is physical (although one's intuitions may be triggered more by the reversed claim that winning a game in your casual football league does not matter anymore if the game is physical rather than virtual). That example is of a paradigmatically physical activity, but there are many shared activities for which historical expedience seems to be the only compelling reason to engage in them offline in preference to online. For example, gossiping about the activities of a mutual acquaintance is a shared activity, of the kind that builds the relevant bonds of friendship. It is not at all clear that there is any particular advantage to doing this offline rather than online, and indeed, the stereotypical precedent for this kind of activity is that of the teenage child tying up the phone line for hours on end talking with their friends, a precursor to the modern forms of interaction now under consideration.

The proponent of offline friendships may nevertheless appeal to a further characteristic of

offline interaction, namely, that it provides fewer opportunities for deception, or, conversely, it offers more opportunities for us to recognize deception when it is practiced and so to curtail the development of a friendship (upon recognition that one party to it lacks the appropriate motivations for the development of the friendship). To continue with the example of the football game, it is easy to be sure that your opponent is who they say they are when you can see them and less easy when you can only see their avatar. However, the online football game will now commonly feature both voice and video of one's opponent, such that this too is similar between the domains. That is not to claim that worries about deception are misguided. When entering into a friendship, one must be wary of deception. After all, not every person who claims to want to be your friend means it. These issues of trust and motivation are ones that we have developed an array of techniques to overcome. We rely on an array of indicators such as body language, tone, and inflection in speech in order to determine the veracity of the claims people make to us, and the usefulness of these techniques does not translate smoothly from offline to online interaction. It is much harder, in an online environment, to determine whether those we are speaking with are being truthful, whether about their desires, their motivation, or their descriptions of themselves. There is evidence that as many as a third of people deceive others when making claims online and that people believe that the frequency of online deception is higher than that (Caspi and Gorsky 2006).

Rather than denying that these issues are problematic, the defender of online and mixed-mode friendships can instead appeal to a lack of uniqueness in the problem. That is, while online interactions are vulnerable to deceptions in these ways, the vulnerabilities are, increasingly, the same vulnerabilities that offline interactions have. As the available modes of online interaction expand, and as technology improves, we are becoming better able to rely on offline cues in online spaces. Voice technology and video technology give us access to relevant information on tone, inflection, and body language. Further, what we do online has changed. We can and

commonly do engage in shared activities online, in ways that were not possible, or were not common, in the relatively recent past. Shared activity is an important tool for determining the veracity of the claims someone makes about themselves, as it is hard to sustain a deception (harder still, the more complex the deception) while under pressure to engage with others. So, in online as in offline interactions, it is difficult for participants to present the "carefully constructed self" that Cocking and Matthews claimed prevents friendship formation online (Cocking and Matthews 2000). While people develop closeness or intimacy in online settings in different ways to those they utilize offline, it does not seem to be any less fulfilling once established. It appears that, at the least, people take their online relationships to be as real, close, and important as their offline ones (McKenna et al. 2002).

So, there is a problem with discerning between true and fair-weather friendships. It used to be the case that it was significantly easier to make the relevant judgments in an offline environment than an online environment, due to certain contingent features of available online environments which rendered them inferior at providing opportunities to judge things like motivation and character. However, these contingent features have been removed or diminished by the development of new technologies and by increases in the volume and kind of information that online media transmit. So, even if for any given online friendship, the chance of it turning, with appropriate time and effort, into a genuine friendship, is less than the chance for any offline friendship, this is insufficient reason to prevent us from engaging in the attempt. There are more opportunities online, and with a wider range of people, such that at least some of the necessary preconditions of genuine friendship are more likely to be fulfilled by those one meets online than those one meets offline.

It may still be that the difficulties are greater in online than in offline friendships, but the difficulties are now recognizably of a kind with those we have historically faced when developing friendships, and they are appropriately responded to in

the same way – we factor the considerations into our behavior; we build up a body of evidence, over time and in a variety of circumstances regarding how our friends behave; and we constantly revise our conclusions regarding how strong our friendship is in light of this evidence. The capacity to develop true friendships exists both in the offline and the online world, and whether that capacity is achieved is a matter, not of the mode of interaction but of the friendships in question and the participants therein.

Maintaining Friendships

Friendships do not simply exist. Rather, they must be maintained by all parties if they are to remain robust. This requires a range of behaviors on the part of friends to continue and to develop the relationship they have, and these behaviors will be both routine and strategic (Oswald et al. 2004). The modern world has characteristics that both aid and impede this friendship maintenance. For example, it is comparatively common now to move between cities, states, or nations during the course of one's life. Each such move leaves behind the friends one has made in a particular place. Historically, such drastic upheavals with their resultant changes to friendship relations were uncommon. So we might think that modern life makes the maintenance of these life-long friendships more difficult. However, the rise of technology-mediated communication allows for the maintenance of friendships in virtual rather than physical space, in ways that were difficult or impossible in the recent past. This allows individuals to maintain friendships that would previously have had to be abandoned.

Analyses of the value of online friendships frequently fail to consider virtual worlds holistically. Rather, they examine particular subdomains of virtual space, such as Facebook, e-mail, or Twitter, and conclude that as stand-alone systems, these lack the features which enable the development of strong friendships (see Condella 2010; Vallor 2012). But these interfaces are not stand-alone systems. They are interrelated, such that one's online friendship tracks over a variety of domains

and builds upon them. The correct comparison is not "Facebook versus the physical world" but "offline versus online" or "Facebook versus the local pub." The comparison of particular online subdomains to the physical world at large is a rigged one, unfair in its choice of starting points. Facebook, for example, is an aspect of an online friendship, just as your social football team is an aspect of an offline friendship. Neither is complete in isolation. We should, in this context, consider virtual spaces to be "third places" which provide an environment of "informal sociability" in which friendships can be maintained and developed (Steinkuehler and Williams 2006). They are, in other words, serving the function that pubs and coffee shops serve, but doing so online.

This characterization of online spaces points to a key benefit of online interaction. Online interactions enable the maintenance of friendships in the absence of continued physical interaction. Whereas previously an old college friend who moved abroad to study or teach at a different institution would have fallen out of touch with you (or at the very least have had significantly fewer opportunities to maintain contact and had these opportunities only in a very limited set of ways), they are now able to maintain a broad and frequent range of interactions. While you may now go years without being physically co-located, you have a preexisting friendship relationship and an understanding, dependent on the quality of your friendship, of the friend's character, motivations, and goals. A sudden flurry of Facebook activity might mean that your friend is compensating for something that has occurred to them in real life, perhaps homesickness, and you can address your enquiries to this end. Without the knowledge formed through the offline relationship, this option would not be available, but without the online medium, you would no longer be in a position to know that your friend has these concerns. By maintaining offline relationships in online environments, that is, by turning these friendships into hybrid or mixed-mode friendships, you are able to keep in closer contact with your friends through social media and other online communication than was previously possible.

Conclusion

The rapid pace of technological change in modern life has introduced many significant difficulties for conceptions of friendship. The standard means of the development of friendships, namely, through interaction with potential friends in the offline world, have been supplemented by a hybrid interaction involving both offline and online interactions, and by a set of purely online interactions, entirely divorced from the offline world. Thus, we now have three means to friendship, rather than one. This expansion has been contested, in the first instance, by those who claimed that there was something unique about the offline world such that friendships could develop therein but not develop in the online world and in the second instance by those who claimed that there was something superior in a friendship developed offline. The best available candidate for uniqueness in offline friendships arises from a distinction between kinds of friendship, which is found across the range of academic disciplines in which friendship is discussed, beginning with Aristotle, who distinguished between higher-order friendships of virtue and lower-order friendships of utility and pleasure, and present through to modern psychology, where David Buss distinguishes between fair-weather friendships and deep/true friendships. The idea is that offline friendships offer opportunities to develop the strong kinds of friendship, which are absent in online friendships. However, even this claim to uniqueness is undermined by the evidence of friendship development in hybrid and purely online environments. At best, it seems as though it may be somewhat easier to develop true friendships in the offline world than it is via online interactions alone. In such a situation, hybrid friendships appear superior to either offline or online friendships, in the sense that they offer a higher chance of developing into true/deep friendships.

The standard view overstates the value of offline friendships, as most do not result in these strong friendships that are so desirable. It is as yet unclear whether the optimal approach to friendships involves concentrating on success rate or total number of successes, where success equals

the development of a higher-order friendship. It may well be that the success rate of offline friendships is higher than that of online friendships, even significantly so. However, online friendships are sustainable in much greater numbers, and it may be that mixed-mode friendships offer both a higher chance of development into deep friendships, and are available in larger numbers, than are offline friendships (although these would still be available in smaller numbers than are purely online friendships).

There is also a tendency in the literature to worry about the extent to which online friendships are replacing offline friendships. This concern appears misguided; as for most people, friendships are maintained in large part online but are formed offline; thus, they are mixed-mode friendships. In supplementing offline friendships with online components, and in meeting online friends in the offline world, mixed friendships are replacing both. Further, as online interactions become ubiquitous, the argument threatens to resolve itself, simply by transforming all our interactions into technologically mediated ones. As people age in the presence of online environments, relationships formed or maintained in them will become more common, less surprising, and more accepted.

Frontal Cortex

Darren W. Campbell and Zhongjie Bao
Nipissing University, North Bay, ON, Canada

Synonyms

Anterior cerebral cortex; Frontal lobe; Pallium; Pre-frontal cortex

Definition

The frontal cortex is the anterior portion of the neocortex, and select structural and functional

differences exist across species. The frontal cortex serves many complex cognitive, social, and language functions, such as complex sequence learning and self-control.

Introduction

Given the complexity, sophistication, and relative dominance of humans compared to other primates and mammals, a common question has been: *What gave humans the evolutionary advantage?* The answers are clearly not superior strength, speed, endurance, or physical size. The answer is commonly assumed to be that human intelligence and exceptional communication skills underlie human dominance. Thus, comparative studies have focused on differences in brain sizes, structures, and functions as probable explanations for human dominance.

The frontal cortex, in particular, is thought to underpin these comparative differences. In humans, the frontal cortex is the largest lobe of the neocortex and is commonly assigned primary responsibility for many complex cognitive functions (e.g., complex problem-solving, and thinking about thinking) and language functions (e.g., symbolic representations of abstract concepts and future scenarios and subtle social messaging; Badre 2008; de la Vega et al. 2016). From an evolutionary or phylogenetic perspective, the frontal cortex is considered the most recently developed brain region (Teffer and Semendeferi 2012). Similarly, from a developmental or ontogenetic perspective, the frontal cortex is one of the last brain regions to reach full maturity (Johnson et al. 2009). This combination of features suggests that the frontal cortex, in particular the prefrontal cortex, is one of the most important brain structures that separates humans from other primates (Teffer and Semendeferi 2012) and may, in large part, account for the human evolutionary advantage.

Frontal Cortex Anatomy

In the human cerebrum, the frontal lobe lies anterior to the central sulcus, superior (on the lateral

surface) to the Sylvian fissure, and superior (medially) to the eyes and nasal cavity. Major sections of the frontal cortex include the inferior, middle, and superior (lateral) gyri and the orbitofrontal (medial) gyri. The frontal cortex also can be subdivided according to its cytoarchitectural organization (i.e., cellular tissue).

German anatomist Korbinian Brodmann developed a cytoarchitectural brain map with 52 topographical subdivisions of the human neocortex identified with numerical Brodmann Area (BA) labels (Verkhatsky 2006). The frontal cortex includes several major cytoarchitectural regions. The precentral gyrus or primary motor cortex (BA 4) is anterior to the central sulcus. The adjacent, anterior section includes the supplementary motor cortex (superior and medial, BA 6), the premotor cortex (lateral middle BA 6), and Broca's language production area (BA 44; Caplan 2006). Anterior to these latter regions is the prefrontal cortex (PFC) which represents a cytoarchitecturally diverse set of subregions (Murray et al. 2016; Petrides et al. 2012) including the dorsolateral PFC (BA 9 and 46), medial PFC (BA 25 and 32), and orbitofrontal cortex (BA 11, 12, 13, and 14). The anterior tip of the frontal cortex is the frontopolar cortex (BA 10).

Note, the frontal cortex does not function in isolation. It is structurally interconnected into functional networks with other brain regions. These networks support several adaptive functions (Jung et al. 2017; Medaglia et al. 2015; Racz et al. 2018; Smith et al. 2013).

Evolutionary Structural Comparisons

Comparing brain structures across species (or phylogenetic classes, orders, families, or genera) is not a simple matter. One common method is to compare overall (or region-specific) brain size relative to body size within the same clade (or genetic lineage; Sherwood and Smaers 2013). Certainly, the human brain is substantially larger than that of other primates, and human heteromodal association areas (which assess and integrate multiple forms of sensory or motor information), such as the frontal cortex, account for

much of this proportionately larger size (Sherwood and Smaers 2013; Verendeev and Sherwood 2017). Some researchers argue that the frontal cortex has expanded disproportionately more than other cortical regions (Sherwood and Smaers 2013; Passingham and Smaers 2014); others disagree (Barton and Venditti 2013; Gabi et al. 2016). Evidence suggests that select areas of the frontal cortex (e.g., frontopolar cortex, BA 10) are larger in humans than other primates, while other areas (e.g., primary motor cortex, BA 4) are not (Sherwood et al. 2012). Thus, humans likely show phylogenetically based volumetric differences in specific frontal cortex regions.

Phylogenetic differences also are evident in the distribution and density of brain-cell types. Research reveals that the frontal cortex of humans has a lower neuron cell-body (gray matter) density and higher dendrite, axon, and synapse density than that of the great apes (Sherwood et al. 2006). Humans also have the highest ratio of glial-to-neuron cells in the dorsolateral cortex (BA 9) relative to the 17 other primate species in their homologous (structurally equivalent) brain regions (Sherwood et al. 2006). In the human brain, glial cells (white matter) are as numerous as neuron cells (Azevedo et al. 2009), and emerging evidence indicates that glial cells serve higher cognitive functions not merely neuron-support functions (Han et al. 2013). These differences in cellular structures are hypothesized to reflect greater intracortical connectivity in humans compared to other primates (Verendeev and Sherwood 2017).

Evolutionary Functional Comparisons

Investigating functional differences across diverse species is quite challenging (Wilson et al. 2017). The investigations require measures which can be performed by creatures with very different physical capabilities and perceptual systems (e.g., birds, rodents, dogs, elephants, and primates), while representing comparable underlying information processing demands. Below we identify two measurement designs and core functions

which reveal phylogenetic differences in frontal cortex functioning (MacLean et al. 2014; Wilson et al. 2017).

The first measurement design represents sequence learning or the recognition of patterns (e.g., expected sequences of sounds, images, or multimodal experiences; Wilson et al. 2017). Once a species has recognized and learned a sequence, they respond in a predictable manner. If new events violate the learned pattern, adaptive and observable behavioral and neural changes are expected. If a species does not show a change to pattern violations, this lack-of-change implies that the creature did not detect (i.e., learn) the pattern.

A systematic evaluation of sequence learning across primate families and subfamilies shows distinct phylogenetic differences in select regions of the frontal cortex (Wilson et al. 2017). For example, various primate families show comparable sequence learning and comparable frontal operculum activation during certain sequences (e.g., temporally adjacent events). This comparability has been interpreted as an evolutionarily conserved function across primates including humans. In contrast, more complex sequence learning (e.g., temporally separated but associated events) is not evolutionarily conserved. Humans show unique complex sequence learning and dorsal PFC (ventrolateral - BA 44 & 45 and dorsolateral - BA 46 & 9) responses not shown in other primates. Wilson et al. (2017) highlight the link between human language processing and the complex learning sequences. They suggest that the dorsal PFC responses support the unique human capacity for advanced language function compared to our primate ancestors.

The second measurement design, which supports across-species comparisons and links to frontal cortex function, represents self-control (Herculano-Houzel 2017; MacLean et al. 2014). This design requires each species first to demonstrate a reward-action response (e.g., observing and retrieving hidden food). Next, for the test trial, the reward is moved to a new location, and the species must avoid searching in the previously rewarded location (e.g., an A-not-B task; MacLean et al.

2014). Thus, the test trial demands self-control and the inhibition of the previously learned (prepotent) response. The number of neurons in the cerebral cortex (or pallium in birds) has predicted across-species, task-performance differences (Herculano-Houzel 2017). For example, great apes with the largest number of cortical neurons performed the best on this self-control task. These results support an evolutionary model of phylogenetically advanced frontal cortex development.

Other Potential Evolutionary Frontal Cortex Functions

Above we presented strong comparative evidence for the evolution of the frontal cortex and select functions. Noncomparative human studies suggest the frontal cortex supports several other evolutionarily relevant functions. For example, a recent study reported that the PFC was activated significantly in response to moral violations between genetically related sisters unlike adoptive, non-genetic sisters (Bacha-Trams et al. 2017), which is consistent with evolutionary models suggesting greater resource allocation among genetic relatives (kin).

The PFC also is associated with risk-taking (Ernst et al. 2006). Risk-taking supports evolutionary functions such as exploration and competition for resources and sexual mates, but excessive risk-taking will undermine survival and reproduction. A recent study illustrated the link between PFC function and sexual risk-taking behavior (Goldenberg et al. 2013) revealing that adolescents reporting risky sexual behavior (i.e., reduced contraception use) showed reduced PFC engagement during a response inhibition task (Goldenberg et al. 2013).

The PFC also plays an important role in determining the motivations and intentions of others (i.e., mentalizing or “mind reading”) as part of a larger network of brain regions (Van Overwalle 2011). The ability to mentalize supports improved prediction of others’ actions which has individual survival and reproduction implications.

Furthermore, Hare (2017) presented comparative evidence that mentalizing underlies inter-individual cooperation and collaboration, which enhances group-level survival and reproduction.

Future Directions

The comparative studies above focus on between-species response differences, while the human studies focus on within-species diversity. Evolutionary insight will be enhanced by incorporating both forms of diversity in future investigations. Given that more neurally complex species likely exhibit greater within-species response diversity than less neurally complex species, we suggest that phylogenetic differences in the structure and function of the frontal cortex will prove relevant to future comparative studies of within-species response diversity.

Definition

As ethanol provides cues to fruit ripeness, the human penchant for consuming alcohol may be a by-product of adaptive fondness for ripe fruit.

Introduction

Alcohol pervades most, if not all, human cultures, and its consumption is regarded as a desired accompaniment to a wide variety of activities. From serving as a social lubricant to playing a role in addiction, many researchers have taken an interest in studying how alcohol is consumed and the consequences of that consumption, resulting in an impressive literature on alcohol. More elusive, however, are explanations for why humans as a species consume alcohol at all despite its significant toxicity (Brooks 1997). The current entry describes the hypothesis put forth by Dudley (2000) that alcohol (ethanol) tolerance and consumption may have emerged as a by-product of our ancestors' adaptive penchant for ripe fruit.

The Evolution of Frugivory Diets

According to fossil records, hominoids have historically survived on a diet consisting

mainly of fruits and plants (Andrews 1981). As descendants of the hominoid line, all modern apes, including humans, are similarly adapted for frugivorous diets. Primates such as the lowland gorillas, orangutans, and chimpanzees have all been observed to consume a wide range of fruits in copious amounts (Rodman 1977; Tutin et al. 1991).

Fruits offer the highest dietary benefits when they are ripe. When fruits ripen, a variety of changes occur. Starch is converted to sugar, resulting in a hike in sugar concentration levels and an increase in sweetness. Frugivores are adapted to find the sweet taste of sugar palatable, which then motivates them to seek and consume fruits particularly when those fruits are in a ripened state where caloric and nutritional content is highest. Other biochemical processes that occur during ripening, such as changes in acidity, color, aroma, and texture (Dudley 2004), also entice frugivores' consumption of ripe fruits. In return, frugivores aid fruits and plants in seed dispersion through a mutually beneficial coevolutionary process. Indeed, fruits that are unripe and carry seeds that have yet to mature have chemical and physical safeguards to prevent untimely consumption by frugivorous seed dispersers (Benner et al. 2002).

Ripened fruits, however, are not always accessible or available, especially in tropical forests where harsh or sporadic weather patterns can hinder fruit development (Leigh 1999). Coupled with intense competition between species of frugivores for scarce ripe fruit, frugivores evolved to be extremely competent foragers. It has been argued that the advanced cognitive and visual capabilities of frugivorous primates are attributable to the selection pressures brought on by the desire for ripe fruit (Milton 2006).

Alcohol Consumption as a Byproduct of Frugivory Diets

Noting the adaptive challenge of acquiring and consuming ripe fruit, Dudley (2000) surmised that frugivores likely evolved to exploit cues

that could facilitate the acquisition and intake of optimally ripe fruit. Fermentation occurs during fruit ripening, which is a complex biochemical process whereby yeast feeds on sugar and produces ethanol. Through fermentation, the odorous plumes of volatile ethanol that emanate from ripe fruit may serve as far-ranging olfactory signals for frugivores. Moreover, ethanol has a distinct taste, which can serve as an additional indicator of ripeness alongside the fruit's sweetness. Thus, utilizing the smell and taste of ethanol enables frugivores to predict a fruit's caloric value (Singh 1985), and frugivores that could detect the odor of fermenting fruit from afar also had a better chance of acquiring the nutrition and calories needed for survival.

Furthermore, as fruits that are optimally ripe are likely to be seized and consumed quickly, many frugivores have to settle for leftover over-ripe fruits that contain substantial amounts of ethanol (Dudley 2004). When metabolized, the caloric content of ethanol is estimated to be 7.1 kcal/g, which is actually higher than that of carbohydrates. As some ethanol consumption may have been unavoidable and ethanol can also provide a source of nutritional supplement, frugivores possibly evolved to be somewhat tolerant of ethanol's toxicity. As descendants of early hominoids who may have evolved to be amenable to ethanol as a by-product of pursuing frugivorous diets, humans may likewise be adapted to not only tolerate the toxicity of ethanol but also have a taste for it.

Conclusion

The frugivory by-product hypothesis suggests that alcohol consumption in humans and our subsequent fondness for the substance may originate from our frugivorous ancestral heritage. Through selection pressures borne from the need to acquire nutritious food sources, frugivores may have evolved to respond favorably to ethanol in order to find and consume ripe fruit. Patterns of alcohol use by humans in contemporary environments may therefore reflect a co-option of ancestral nutritional strategies,

specifically the adaptive sensory biases that lead frugivores to associate ethanol with nutritional reward.

Genetic relatedness; Sibling relationships

Definition

Full siblings share the same biological mother and father, maternal half-siblings share the same mother only, and paternal half-siblings share the same father only. Therefore, full siblings share, on average, 50% of their genes with one another and half siblings share approximately 25%. Because individuals share more genes with their full siblings than their half siblings on average, full siblings are predicted to invest more in each other compared to half siblings. By investing in full rather than half siblings, individuals can more effectively increase their own inclusive fitness.

Introduction

Individuals tend to invest time and resources in their kin. Evolutionary researchers have explained this by inclusive fitness theory (Hamilton 1964), which assumes that the degree of genetic relatedness is associated with the investment directed

towards relatives. Individuals share approximately 50% of their genes with full siblings and 25% of their genes with half siblings. Therefore, according to inclusive fitness theory, individuals should invest more in their full siblings than in their half siblings.

Sibling relationships do not, however, include only altruistic support but also competition and conflict (Tanskanen et al. 2017). Sibling conflicts may reflect competition over parental resources and are most common during childhood and adolescence when parental investment matters the most (Salmon and Hehman 2014). Conflicts may especially occur when siblings are the same gender and the age difference between the siblings is moderate (Pollet and Hoben 2011). Although conflicts between siblings can also occur in adulthood, adult siblings typically provide resources and emotional help to one another, meaning that adult siblings often form social support systems (Pollet and Hoben 2011). In this entry, we consider relationships between full siblings and half siblings from an evolutionary perspective and take the ambivalent nature of this social tie into account.

Cooperation Between Full and Half Siblings

An increasing number of studies show evidence for the inclusive fitness theory prediction that the degree of genetic relatedness will influence the investment that individuals direct towards their kin among humans and nonhuman species (Salmon and Shackelford 2011). Moreover, studies have shown that the degree of genetic relatedness may play an important role in sibling relationships in different populations (Pollet and Hoben 2011). Full siblings can be favored also in situations where cultural values are against preferring full siblings at the expense of half siblings exist in the population (Jankowiak and Diderich 2000).

In terms of half sibling relationships, an important difference exists between maternal and paternal half siblings. In modern Western societies, children tend to stay with their mothers if the parents separate, meaning that maternal half

siblings are more likely to be raised together than paternal half siblings. Since maternal half siblings often spend their childhood in the same household with each other, they may have more shared life experiences than paternal half siblings who have often spent their childhood in different households. Evolutionary psychologists have identified two human kin detection mechanisms in the case of human siblings that may both typically exist in the case of maternal half siblings, but not in the case of paternal half siblings. These are maternal perinatal association (e.g., seeing one's own mother nurse another child), which is a cue that can only be used by older siblings, and childhood co-residence duration (Lieberman et al. 2007). Therefore, one may assume that maternal half siblings have better relationship quality than paternal half siblings.

Consistent with this assumption, studies have found that maternal half siblings tend to be closer to each other than paternal half siblings (Pollet 2007; Tanskanen and Danielsbacka 2014). Moreover, unequal parental treatment as perceived by the children could mediate the sibling relationship quality between maternal half siblings and full siblings (Danielsbacka and Tanskanen 2015).

The relationship quality between full and half siblings can also be extended to siblings' children. Individuals share an average of 25% of their genes with full siblings' children and 12.5% of their genes with half siblings' children. The inclusive fitness theory predicts that more investment should be directed towards nieces and nephews via full siblings than nieces and nephews via half siblings. Consistent with this prediction, a previous study found that individuals have more contact with their nieces and nephews via full siblings than via half siblings (Tanskanen and Danielsbacka 2014).

Qualitative differences in full and half sibling relationships have also been found among non-human species. Holmes and Sherman (1982) investigated Belding's ground squirrels where the female offspring tend to live in the same nest with both their full and half-sisters. In this species, female full siblings have been found to be more cooperative and less antagonistic towards one another compared to female half siblings.

Conflicts Between Full and Half Siblings

Evolutionary researchers have explained conflicts between siblings by the sibling conflict hypothesis, which is an extension of the classic parent-offspring conflict theory by Trivers (1974). Based on this theory, parents are expected to invest as many resources as necessary to guarantee their offspring's survival. In terms of parents' fitness benefits, the optimal level of parental investment in any particular offspring is related to the parents' ability to provide investment in either this offspring or others. From a parental perspective, investing all resources in only one offspring may not be the most evolutionary beneficial strategy. At the same time, offspring are "programmed" to acquire as much parental investment as possible, even at the expense of the resources that his or her siblings receive. This is because the child is 100% related to himself or herself but only 50% related to his or her full siblings (if the child does not have a monozygotic twin).

According to the parent-offspring conflict theory (Trivers 1974), siblings are predicted to compete with each other over parental investment, creating conflicts between siblings. Sibling competition ranges from small disagreements to aggressive interactions including fights and even siblicide. Siblicide is more common in birds (Mock and Parker 1997) but rare in most mammals, including humans (Hudson and Trillmich 2008). In contemporary human populations, less than 2% of all homicides are found to be siblicides and siblings are more likely to kill a third party together than each other (Daly and Wilson 1988). However, milder conflicts and disputes between siblings can be defined as a natural part of sibling relationships across human populations (Pollet and Hoben 2011).

The degree of genetic relatedness is assumed to be associated with conflict occurrence in that the degree of relatedness increases the probability for decreased conflicts (Salmon and Hehman 2014). This means that half siblings should have more conflict than full siblings. Consistent with this prediction, toddlers who are living in the same household with their full siblings only have been found to have a lower likelihood of injuries

compared to toddlers living with both full and maternal half siblings (Tanskanen et al. 2015). However, a set of previous studies has shown that contrary to this prediction, full siblings tend to have more conflict with each other than half siblings (Salmon and Hehman 2015; Tanskanen et al. 2016; Tanskanen et al. 2017). These findings have been explained by the diluted competition model (Tanskanen et al. 2017). Full siblings compete over the investments of the same two parents, but half siblings have another parent who may invest resources in him or her. This means that the investment received from the nonresident parent may dilute the sibling competition among half siblings.

Conclusions

Relationships between siblings can last for a lifetime, making sibling ties the longest-lasting social bonds in the course of human life (Cicirelli 1995). However, although siblings form important social ties and support systems, conflicts are also a built-in aspect of sibling relationships. In this entry, we have considered sibling cooperation and conflict while taking genetic relatedness into account.

According to previous evidence, important differences are apparent in full and half sibling relationships. Full siblings tend to have more contact and tend to be emotionally closer with each other compared to half siblings. These findings are consistent with the inclusive fitness theory, which assumes that when the degree of genetic relatedness between individuals increases, so does the relationship quality between them. Full siblings are also found to have more conflicts with one another compared to half siblings. This finding can be related to diluted competition. Based on the fact that half siblings can often receive investment from a nonresident parent, full siblings typically compete for the investments of the same two parents.

Studies have also shown qualitative differences between maternal and paternal half siblings. Maternal half siblings are found to have closer relationships to each other compared to paternal half siblings. In contemporary societies, children

usually stay with their mothers if the parents divorce, meaning that maternal half siblings typically spend their childhood in the same household. In contrast, paternal half siblings are more likely to live in different households. Therefore, the differences in maternal and paternal half sibling relationships could be related to human kin detection mechanisms that are based on childhood co-residence duration and maternal perinatal associations.

To conclude, studies have shown that genetic relatedness tends to shape sibling relationships. However, longitudinal studies are needed to investigate how relationships between full and half siblings change over time and if any differences emerge in these changes based on genetic relatedness.

Function of Adoption

Anthony A. Volk
Department of Child and Youth Studies, Brock
University, St. Catharines, ON, Canada

Synonyms

Adaptation; Alloparenting; Family; Nepotism

Definition

What is the purpose of caring for children who are not one's biological children?

Introduction

On the surface, adoption is something of a paradox from an evolutionary perspective as it appears to run counter to the evolutionary principle of passing on copies of one's own genes as one instead invests time and resources into other people's offspring (Hamilton 1963). However, adoption is nearly ubiquitous across known cultures, suggesting that it might have some evolved component (Silk 1990; Volk 2011). Indeed, adoption appears to serve multiple functions that can be adaptive or maladaptive, depending on the contextual point of view. In particular, it can serve as an altruistic parental substitution, a form of kin support, or as a form of social networking.

Altruistic Parental Substitution

The most widely familiar modern function of adoption is as an altruistic substitution for biological children, typically due to infertility or child mortality (Volk 2011). Under these circumstances, parents are strongly motivated by a (potentially innate) desire to raise children, but do not have any biological children of their own to whom they can apply this motivation. In modern society, such parents are typically of Western descent and are wealthy, educated, older (late 30s to early 40s), and highly motivated to care for a child (Hamilton et al. 2007). Thus, this form of adoption is an attempt to replace biological parenting with a socially equivalent parenting of a typically unrelated child. The adaptive function of this behavior is questionable as it typically does not translate into the transmission of one's genes. Instead, it may represent a mismatch between an adaptive, evolved desire to have a biological child and the inability to do so.

Interestingly, parents who adopt unrelated children are often keenly motivated to create the

social and psychological impressions of relatedness and incorporation into their kinship circle (Howell 2003, 2006). This further reinforces the hypothesis that the function of this kind of adoption is to replace biological children with distantly related or unrelated children (Silk 1990). Indeed, among some societies, childlessness is viewed as immoral, leading wealthy infertile women to choose to adopt a child to maintain the social structure of motherhood (Talle 2004). Sometimes this adoption occurs despite the protests of the biological mother, whose husband forces the exchange of their child for material gains (e.g., a cow; Talle 2004). This form of parental substitution may not be as altruistically motivated given the social pressures associated with the decision.

Traditionally, adoption of unrelated children in modern societies has been viewed as a mix of risk factors. While adopting parents are often well equipped mentally and economically to adopt a child, adopted children typically have a higher risk of preexisting developmental issues (Palacios and Brodzinsky 2010). The latter can potentially lead to more negative outcomes. Interestingly though, in Western societies, the drive to provide optimum care for all children can actually lead parents to provide more resources to their adopted versus their biological children (Gibson 2009). While this appears to be maladaptive behavior from an evolutionary point of view, it is likely motivated by the same mechanisms associated with parental solicitude that initially resulted in the desire to adopt and that respond more vigorously to the typically greater needs and poorer outcomes of adopted children in Western countries (Gibson 2009). In contrast, in non-Western countries where parental resources are scarcer, adopted children typically receive fewer resources than biological offspring (Silk 1990).

Kin Support

Another function of adoption is kin selection, or the support of individuals who share related genes. Evolutionary theory suggests that parents should invest in related children so long as the cost to themselves (i.e., their own genes) is offset

by the benefit to the shared genes in the related children (Hamilton 1963). So from a crude evolutionary point of view, it is worth sacrificing 1/5th of one's time and energy to raise a niece or nephew who shares 1/4th of one's genes. Thus the degree of support provided to adopted children in this context likely depends on how closely they are related (e.g., a niece vs. a second cousin) and how costly the investment will be to the adopting parent(s) (e.g., if they don't have any children of their own, then the costs will be lower and the benefits greater; Rawson 2003). Even in modern contexts where the primary motive is altruistic parental substitution, the success of an adoption is based on kinship networks of support (Johnston 2012), highlighting the role of kin in any adoption process. The critical role of human nonparents as alloparents who support the upbringing of most children (Hrdy 2009) makes it a very small leap from many adults providing some alloparental care to some alloparents providing all of the parental care (i.e., adoption or fosterage).

The most likely circumstances for this form of adoption are when one or both of the parents die (Halbmayer 2004), a not uncommon event in the evolutionary past (Volk and Atkinson 2008). Particularly in an evolutionary context, children without their parents (and especially without their mother) face greatly increased levels of mortality (Sear and Mace 2008). Under these circumstances, the related adopting parent enables the survival of the related child (a large benefit) for a relatively modest cost (a smaller cost than birthing and raising one's own child – particularly if the child is older). This is likely a relatively ancient pattern of behavior (Hrdy 2009) as chimpanzees have been observed to adopt younger siblings if they are maternally related (Hobaiter et al. 2014).

Further, in humans, this function of adoption is not limited to orphaned children as it may also apply to children whose biological parents lack the mental, emotional, and/or economic means of caring for them (Volk 2011). This pattern is commonly observed in fosterage systems (caring for the child of a living parent) where children are placed in the care of a related individual (Scelza and Silk 2014). In North America, just under half

of all adoptions are by kin who are supporting children with a living parent (Stolley 1993) while 31% of fostered children are raised by kin (Testa 2004). These numbers might well be higher as many families rely on informal systems of adoption and fosterage to support ill-equipped biological parents. This too is a relatively ancient practice, as it is fairly widely practiced among hunter-gatherers and agriculturalists (Alber et al. 2010; Silk 1990; Volk 2011). It was also extensively practiced in seventeenth-century Europe when poor parents gave up their children to wealthier relatives with the hopes of eventually being able to reclaim them under better economic conditions (Cunningham 2005). Similar practices were common in Brazil until recent times, leading to tragic modern scenarios where some mothers give up their children for others to raise only to find that when their economic circumstances have improved, the government no longer allows them to reclaim their children (Fonesca 2004). Overall, these patterns of kin adoption or fosterage allow broader family networks to adaptively pool their resources in order to optimize their investment in the next generation.

Perhaps the most dramatic example of kin support fosterage comes from the Baatombu of Northern Benin. Traditionally, almost all Baatombu children were raised by relatives other than their biological parents (Alber 2003; Alber et al. 2010). Boys were raised by male relatives and girls with female relatives, with the father's side of the family getting the firstborn, the mother the second, etc. (Alber 2003). Interactions between the birth parents and their children were strongly discouraged in order to maintain the adopted kin structure. The Baatombu believed that this served two important purposes. First, it promoted child survival by ensuring that only adults with sufficient resources were entrusted with raising a child. Second, it promoted within-family solidarity by reinforcing the kin network by sharing its most precious resources – their children. So a process of kin selection is reinforced not only by increased child survival and thus shared genetic transmission, but also by using adoption to build stronger familial social networking.

Social Networking

This kind of social networking represents the third potential form of adoption and is the most prevalent function of nonkin adoption among many traditional cultures. Typically, it serves to reinforce social bonds and/to provide additional resources to the adopting family.

In the case of resources, children are valued primarily for their current and/or future capacity for labor. A typical example would be for economically poor biological parents to exchange their child for resources with wealthy and/or elderly fostering parents (Kirkpatrick and Broder 1976). The benefit to the latter would be the free labor provided by the adopted child. While this is to a degree a form of childhood servitude, most cultures enforce rules on how adopted children are to be cared for and treated (Talle 2004; Testa 2004). If the adopting parents violate these rules, then the biological parents can cancel the contract and reclaim their child. Thus, it is typically a reciprocal agreement whereby poor biological parents get much-needed resources and are relieved of the costs of raising a child while wealthy/elderly adopting parents are able to translate material resources into labor outside of a free-market economy.

However, there are some potential variations to this theme. For example, among the Ifaluk of the Western Caroline Islands, wealthy individuals give away their biological children to poorer adopting parents (Betzing 1988). This does not appear to be a form of reciprocal altruism. Rather, it appears to be an effort by elites to translate their economic and social power into parasitic brooding. That is, the biological parents force less powerful adopting parents to bear all of the costs of raising the adopted child without offering any benefit in return. While perhaps morally dubious, this does offer powerful individuals a means of increasing their potential reproductive success by dramatically passing off the costs of raising their biological offspring to unrelated individuals.

The final form of social networking that was common among nonkin was adoption as a form of alliance creation or maintenance (Volk 2011). The general idea in this context is that if an individual

raises another person's child, then the biological parent has a vested interest in the success and well-being of the adoptive parent as they are responsible for raising their biological child. Many native North and South American groups used adoption as a means of ending blood feuds as well as integrating captive children into their new groups (Volk 2011). Similar practices were observed among other violent hunter-gatherer groups that practice blood feuds (e.g., New Guinea Highlanders). The practice was also quite common in historical cultures ranging from ancient Rome to medieval Europe to late Imperial China (Cunningham 2005; Hsiung 2005; Rawson 2003; Volk 2011). In all of these cases, kin selection was used as a tool for both reducing tensions and violence between groups and promoting new social networks by offering one's children as a guarantee for one's social cooperation and against one's use of violence. It has also been used by some cultures as a means of fostering marriage arrangements (Volk 2011). This can either be through exchanging children who are to be later married or by adopting a child who is meant to serve as a future wife when they are older (Halbmayer 2004).

Conclusion

Adoption is a complex behavior that has roots in both reciprocal altruism and in kin selection. It is a flexible tool that can serve one or both functions within or outside of family networks. From an evolutionary perspective, it is a small leap from a general propensity for alloparenting to a more intensive investment in adopted or fostered children. The sheer versatility of the functions of adoption and fosterage suggests it is an ancient and fairly ubiquitous means of promoting individual and familial evolutionary fitness. It is ironic that the most familiar form of adoption in modern Western society is perhaps the least evolutionarily motivated and viable function of adoption (altruistic parental substitution). Yet it is perhaps the most socially altruistic expression of the evolved human desire to protect, care for, and spend enormous time and emerging raising biologically unrelated relatively helpless infants and

children. Overall, the adaptive and maladaptive functions of adoption clearly reinforce Hrdy's assertion (2009) that humans really are the most social and alloparental ape.

Function of Dominance

Power; Prestige; Social status; Status

Definition

Dominance describes a method for obtaining status, involving priority access to limited resources through the use of fear and coercion.

Introduction

Dominance reflects a strategy in which intimidation and force are used to achieve high status within a group. Leadership, in this case, is attained through fear and maintained through deference that is coerced, rather than freely conferred (Case et al. 2018). An alternative strategy for achieving status is prestige, in which deference is freely granted toward an individual who displays competence and knowledge in valued domains (Henrich and Gil-White 2001). Positions of prestigious leadership are maintained through contributions toward the well-being of the group, personal sacrifice, and maintenance of positive social relationships with subordinates. The fact that both routes are successful for achieving status implies that there should be contextual determinants of the effectiveness of each strategy. Particularly in cases in which assertive, forceful action can lead to the greater accumulation of scarce resources or neutralizing threats posed by a competing group, dominance-based strategies should be more functional than prestige-based strategies.

Characteristics of the Hierarchy

The time course over which social influence within a group emerges has important implications for the relative function of dominant traits in attaining status. Within a specific competence domain of critical importance to a social group – for example, hunting skills in a subsistence economy – high status may emanate from demonstrably superior skills and success. However, in newly formed or less cohesive groups, where casual or shorter-term interactions are the norm, there is much less opportunity for group members to evaluate individual variation in competence in critical

domains. In such cases, motivated individuals can achieve influence through the expression of dominance behaviors because, in the absence of evidence to the contrary, their assertive and forceful nature is assumed to derive from actual superiority—despite the lack of evidence for actual competence (Anderson and Kilduff 2009). Once the group becomes more established or cohesive, however, influence may shift toward individuals who are more skilled in that particular domain.

The distribution of resources within a hierarchy may provide another avenue for dominant individuals to attain influence. Unequal access to resources, in which benefits accumulate at the top of the hierarchy, creates competition for leadership roles. Hierarchies characterized by high levels of inequality, therefore, should favor individuals expressing dominance behaviors because such strategies facilitate the monopolization of resources, leading to downstream fitness benefits such as increased reproduction (Ronay et al. 2018). These strategies are evident in baboon colonies in which food sources are relatively dispersed and female reproductive fertility is both brief and easily recognizable. In such ecological conditions, scarce nutritional and reproductive resources are easily monopolized by the largest and most aggressive males. A similar pattern can be seen in certain small-scale human societies, such as the Yanomamö hunter-horticulturists located in the Amazon basin. The sedentary Yanomamö rely on limited access to rivers as a source of protein to supplement their diet. Restricted access to the rivers allows for the monopolization of these resources through violence, and, as a result, power is concentrated with dominant individuals who are capable of obtaining these resources for themselves and their tribes. Reproductive success is also linked to dominance within the Yanomamö, as the number of wives a man has is directly proportional to the number of people he has killed. Dominance, therefore, provides an adaptive advantage in situational contexts characterized by high levels of inequality because it facilitates the acquisition of limited resources.

Group Success

Group members can gain an adaptive advantage by subordinating to successful leaders, provided that the leader's actions coincide with the best interests of the group. Dominant leaders, however, often prioritize the preservation of their power over ensuring group success when their position is uncertain (Mead and Maner 2012). For example, protecting a position of threatened power typically leads a dominant leader to treat group members as threats rather than allies. Leaders may closely supervise skilled group members who have the potential to become competitors for the leadership position. In this way, leaders can monitor and downregulate the threat posed by the skilled individual, thereby protecting their position of power within the group.

Given the propensity for dominant leaders to protect their positions, even at the expense of group success, prestigious leadership is often preferred because their motivation to be respected and appreciated may make them more inclined to behave in ways that benefit the group. The primary route to prestigious leadership involves gaining social approval and support from members of a group. Therefore, prestige-oriented individuals should be highly motivated to achieve and maintain acceptance, and may be highly concerned with how they are perceived (Case et al. 2018). When group success and social approval are aligned, achieving prestige is relatively straightforward. However, sometimes making decisions for the benefit of the group conflicts with the opinions of the group members. In such situations, when forced to make decisions in which the group's collective success is at odds with social opinion, prestigious leaders' decisions depended upon the transparency of the situation (Case et al. 2018). When given the choice of performing one of two tasks, prestige-oriented leaders were more likely to choose the task they believed the group would be most successful at (despite the group members voting for the second task), but only if their decision was kept anonymous from the group. When their decisions were made public, however, prestigious leaders were more likely to ignore their own judgments and pander to the wishes of the group in order

to maintain social approval. Thus, when social approval is at stake, prestigious leaders may make decisions that undermine their group's success. Consequently, endorsing a prestigious leader does not always lead to the best outcome for the group, and, under certain circumstances, a dominant leader may be more advantageous.

In line with this, the presence of a rival group seems to galvanize dominant leaders toward beneficial decisions for the group and away from self-serving ends. For example, during an intergroup competition, dominant leaders no longer closely supervise skilled group members and instead increase their autonomy and allow them to contribute to group success (Mead and Maner 2012). Additionally, in competitive intergroup interactions, dominant individuals are more likely to be elected as a group representative than prestigious individuals (Halvey et al. 2012). In a social dilemma game, benefitting in-group members was associated with perceptions of prestige, but maximizing in-group advantage by either directly harming or reducing shared resources toward an out-group was associated with perceptions of dominance. Furthermore, individuals willing to benefit in-group members at the expense of out-group members were more likely to be elected as a group representative in a subsequent competitive interaction. Therefore, the presence of an external threat makes dominant leaders more attractive, perhaps because they become more concerned with group success and benefitting in-group members at the expense of out-group members.

Methods and Mechanisms for Obtaining Status Through Dominance

Dominance can be used to obtain status via multifarious means, including both behavioral expressions (e.g., aggression) and morphological features thought to reflect cues of dominance (e.g., facial width to height ratio, muscularity, vocal pitch), each of which has been shaped by natural and sexual selection pressures. A full review is beyond the scope of this entry, but a small selection of methods and mechanisms for obtaining status through dominance is provided.

Aggression. Consistent with the notion that dominance is a forceful, fear-based strategy, aggression represents one behavioral mechanism by which dominance can increase individual status within a social hierarchy. Among the Yanomamö, for example, men who have survived multiple ritualized club fights are subsequently admired and feared, resulting in greater status and power (Changnon 1983). Various other studies show a positive relationship between trait dominance and aggression, hinting at aggression's potential utility in gaining status.

Testosterone. Research efforts have also been dedicated to identifying biological mechanisms linking dominance, aggression, and status. One candidate of particular interest is the steroid hormone testosterone. While some work has shown positive correlations between trait dominance and basal levels of testosterone, and between basal levels of testosterone and aggression, others have failed to replicate such findings. Such inconsistencies have been attributed to differences in methodology (e.g., self-report aggression vs. behavioral aggression), and testosterone's dynamic nature, with levels flexibly rising or falling in the face of evolutionarily relevant contexts and cues (e.g., status threats). Indeed, more consistent seems to be that changes in testosterone, rather than basal levels, predict future behavior aimed at gaining or maintaining social status. For example, a rise in testosterone following competition has been found to predict a suite of motivational and behavioral displays, including subsequent competitive motivation and performance, as well as aggression (see Zilioli and Bird 2017). This pattern is consistent with theoretical suggestions that a competition-induced rise in testosterone serves to promote behavior aimed at maintaining social status, while a drop promotes submissive behavior aimed at preventing further loss of status (i.e., The Biosocial Model of Status, reviewed in Zilioli and Bird 2017). Recent work has also examined the causal relationship between testosterone and aggression by using exogenous administration, and findings show that the effects of testosterone on aggression are dependent on certain personality traits. For instance, Carré et al. (2017) found that testosterone increases aggression but only among men with

personalities characterized by high trait dominance and high impulsivity. The extent to which contextual variables (e.g., competition win or loss) interact with the effects of hormone administration and personality characteristics to predict dominant behavior remains to be determined, but there are likely complex interactions between situational, motivational, and physiological variables.

Pride. Certain emotions have also been identified as important to dominance- or prestige-based strategies, with pride in particular being especially relevant to status-seeking efforts. Two distinct forms of pride have been identified, including hubristic pride—characterized by arrogance and self-admiration—and authentic pride, reflecting feelings of confidence and success. Notably, research has found that these two facets of pride differentially relate to status strategies: individuals high in trait hubristic pride self-report and receive higher peer ratings of dominance, whereas individuals high in trait authentic pride self-report and receive higher peer ratings of prestige (Cheng et al. 2010). This work also found that dominant individuals were characterized by a combination of traits such as aggression, narcissism, disagreeableness, and extraversion, whereas prestigious individuals were characterized by traits such as conscientiousness, prosociality, and high genuine self-esteem. Such findings provide evidence to suggest multifaceted contributors (e.g., emotions, personality) to different status-based strategies.

Conclusion

Certain contextual moderators make dominance-based strategies for achieving high status more functional than prestige-based strategies. Specifically, in situations in which the distribution of resources is unequal or the group is newly formed, dominance is advantageous because it signals competence and facilitates the accumulation of resources through force and intimidation. Group members may also reap the benefits of dominant leadership under certain circumstances, such as during intergroup competition. The presence of an external threat alters the focus of dominant

leaders from prioritizing individual status toward group needs and thus may be more functional in terms of facilitating group success compared to prestige-based leaders.

There are a range of behavioral, biological, and personality-based characteristics underpinning dominance behaviors that may facilitate status achievement in these particular contexts. For example, changes in testosterone levels following competition may promote behaviors such as aggression, which are aimed at maintaining social status. Additionally, hubristic pride promotes dominance-related tendencies such as arrogance and narcissism that promote status. These characteristics are particularly functional in achieving status in contexts in which forceful, agentic behavior is likely to result in success, such as during intergroup competition or the accumulation of limited resources.

Ethical intuition; Moral; Moral foundations; Right and wrong

Definition

The functions of morality are understood as the solutions of adaptive challenges in the ingroup-outgroup dynamics.

Introduction

Morality plays a role among humans in functions that are crucial to the evolutionary process of humans as social beings. Group valorization is of great importance for the survival of the species and morality acts in this field. The purpose of this chapter is to provide an overview of the functions exercised by morals in the process of human evolutionary development.

Foundations and Functions of Morality

According to Graham et al. (2013), the idea of human morality is derived from multiple innate mental systems shaped by different evolutionary process. The Moral Foundation Theory (MFT) proposes that morality is intuitive, nonrational, innate, and highly dependent on environmental influences, being a pluralistic theory as a bridge to evolutionary and anthropological approaches to moral judgment. Thus, morality is organized into five main domains or foundations. Each foundation was evolved to solve adaptive challenges or problems and has a specific function in the human behavioral repertoire (Gould and Lewontin 1979). Some of these problems are social and the human mind developed mechanisms to solve them guided by an ethical intuition as the groups and society began to expand (Richerson and Boyd 2005; Tomasello et al. 2005).

According to Haidt (2008), the moral system is an “interlocking sets of values, practices, institutions, and evolved psychological mechanisms that work together to suppress or regulate selfishness and make social life possible” (p. 70). The evolution of morality contributes to enable human life. As a pluralist theory, because there were many recurrent social challenges, so there are many moral foundations (Graham et al. 2013). The five foundations are: care/harm; fairness/cheating; loyalty/betrayal; authority/subversion; sanctity/degradation.

Each one of these foundations has evolved to accomplish specific functions in the evolution process of the human being. The foundation of care/harm has possibly evolved to solve the

challenge of caring for the vulnerable offspring for an extended period of time (Graham et al. 2013). The main function of this foundation is to lead to the disapproval of individuals that cause pain and suffering and to approve those who prevent or alleviate harm. Disapproval of harmful behaviors might be driven by an overarching concern with a vulnerable group; on the other hand, care for vulnerable members also avoids suffering, distress, or neediness and provides protection (Graham et al. 2013; Koleva et al. 2012).

Fairness/cheating or fairness/reciprocity possibly has been triggered by acts of cheating or cooperation by one's own direct interaction partners and might have the function of reap benefits of two-way partnerships (Graham et al. 2013). This foundation can also be understood as widespread intuitions about ingroup-outgroup dynamics and make the individuals sensitive to issues of equality and justice and leads us to frown upon people that violate these principles (Koleva et al. 2012; Haidt 2007). It has evolved in response to the adaptive threat of being exploited by cheaters and increasing one's chances of receiving benefits of cooperation (Haidt 2012).

The third foundation is loyalty/betrayal, which became decisive for survival because its function is to form cohesive coalitions as the humans developed intergroup competitions (Graham et al. 2013). Another function is based on the attachment to groups (e.g., our family, church, or country) that leads to approve those who contribute to the group's well-being and cohesion (Koleva et al. 2012). According to Haidt (2012), this foundation evolved in order to maintain group cohesion by making an individual aware of others that want to hurt or ostracize members of the group.

The authority/subversion foundation forges beneficial relationships within hierarchies (Graham et al. 2013). This foundation is based on the tendency to create hierarchically structured societies of dominance and subordination and had evolved with the function of maintenance of and respect for the social hierarchies, which make the group aware of potential threats to one's status or rank (Koleva et al. 2012, Haidt 2012). This foundation includes approval of individuals who fulfill the duties associated with their position on the

social ladder, for example, by showing good leadership, or obedience (Koleva et al. 2012).

Finally, the sanctity/degradation foundation has the function of avoiding communicable diseases and is the only one for which the original adaptive challenge was not social – it was mainly nutritive challenges (Graham et al. 2013; Haidt and Joseph 2007). This foundation has evolved in response to the danger of pathogens and parasites but also to various social contaminants like spiritual corruption, or the inability to control one's base impulses (Haidt and Joseph 2007; Koleva et al. 2012). Therefore, it makes individuals aware of any potential threats to health and symbolic objects or values (Haidt 2012).

Conclusion

The moral foundations, as innate mental structures, are likely to be the most effective responses to adaptive challenges that humans have faced during the evolution process in the social world (Graham et al. 2013). The most common functions of moralities were developed to solve ingroup-outgroup dynamics and challenges; as Haidt and Joseph (2006) indicated: rearing children and helping kin; selectively cooperating with non-kin while remaining vigilant for cheaters; forming strong ingroups for the purpose of cross-group competition; organizing themselves hierarchically; and attending to each other's physical states and altering interactions and contacts accordingly.

Thus, morality is understood as the result of adaptive processes with the main function of survival and group cohesion. This is a functionalist vision and contributes to understand human behavior and the development of morality based on natural selection and cultural influences.

Department of Psychology,
Stockholm University, Stockholm, Sweden

Synonyms

Behavioral immune system; Parasite adversity;
Parasite-stress theory

Definition

Function of pathogen prevalence refers to the effects of pathogen risk and disease stress on regional variations in mental, social, and personality traits such as intelligence, conservatism, ethnocentrism, religiosity, cultural diversity, and others.

Introduction

Pathogens are organisms that live in (or on) a host organism, at the nutritional and health expense of the host. They can cause the host to suffer a quick and lethal damage or be present for longer (in which case they are often referred to as *parasites*). The function of pathogen prevalence is very well described by Thornhill's and Fincher's parasite-stress theory of values and sociality. All text refers to Thornhill and Fincher (2014a) unless stated otherwise.

Local Pathogens and Local Immunity

Human immune system can vary greatly across regions due to different levels of pathogen prevalence. A good example of this is caste-specific immunity to diseases in India (Pitchappan 2002) or – on an even more local level – village-specific immunity to diseases in Sudan (Miller et al. 2007). History provides even more examples of the drastic consequences for members of isolated groups when they encounter (via trade or conquest) novel groups from other regions. Recently, bacteria thought to kill the majority of Aztecs were traced back to European strain of *Salmonella* (Callaway 2017).

Pathogens are the main drive of evolutionary change in modern humans, being responsible for more evolutionary changes in the genome than any other environmental factor, including climate and geographical and dietary factors. Immunity-related genes are more diverse across regions than are genes related to any other environmental factor (Fumagalli et al. 2011). Moreover, infectious disease was the

largest mortality factor among children and youth in three different ethnographic samples, representative of human evolution steps (Volk and Atkinson 2013).

Regional Variation in Pathogen Prevalence

The Earth differs greatly with regard to pathogen prevalence: low latitudes are areas of higher parasite stress than high latitudes. When living in a pathogen-rich environment, only members of one's own group (ingroup) used to be disease-safe, while members of other groups (outgroups) posed a serious disease threat. Benefits and costs of interactions with outgroups change across regions related to how prevalent pathogens in these regions are. When the pathogen risk is low, the potential disease costs of an interaction with other groups decrease and are outweighed by the benefits (e.g., trade, marriage). Under high parasite stress, societies often take a form of an assortative society: one where individuals mate based on similarity of traits and do so more often than a random mating pattern would predict. What follows as a consequence of pathogen prevalence is also the occurrence of social attitudes such as xenophobia, ethnocentrism, and philopatry, which are components of an assertive society. These attitudes and related practices limit contacts with outgroups, who pose threat from novel pathogens and are more common when parasite stress is high. Local food and hygienic practices often serve to manage local diseases and help preserving the ingroup immunity. Thus, preferring traditional ways of thinking and avoiding foreign ideas can be perceived as defenses against novel parasites brought by outgroups (Kurzban and Leary 2001) and is closely linked to the behavioral immune system. Behavioral immune system is adaptive and comprises psychological and behavioral processes involved in pathogen avoidance (Schaller and Park 2011).

There is a quantitative relationship between the components of assortative society and parasite stress across the world regions. In consequence, high parasite stress areas have more ethnic groups

than low parasite stress areas, as groups tend to merge and dilute more when the risk of catching a disease is lower (Thornhill and Fincher 2014b). While in humans this is related to language and cultural diversity, in other animals, high parasite prevalence is also related to high number of species in a given region.

Functions of Pathogen Prevalence

The mechanisms described in the previous section have multiple consequences for human behavior. Differences in parasite stress have been linked to societal values, such as those mentioned before (xenophobia, ethnocentrism) and many others. To begin with, pathogen prevalence is related to sexual behavior. It influences mate choice preferences: under high pathogen threat, attractiveness of the mate is of special importance as it signals genetic quality; local mating is more popular as well. Parasite stress is also important for sexual restrictiveness. Specifically, high parasite stress is related to more conservative sexual behavior. Second, there are more religions under high parasite stress conditions. Many cultural aspects are thought to rise as a function of pathogen prevalence: (a) collectivism is associated with high parasite stress and individualism with low, (b) high pathogen prevalence regions are more culturally diversified, and (c) more conformity is present when pathogen risk is high. Last but not least, nonhuman interactions can also be influenced by pathogen prevalence, for example, in terms of attitudes to and presence of pets (e.g., dogs). In high parasite stress regions, where these animals can be hosts to more pathogens, human contact with them is less frequent, and keeping them at home is less popular.

Personality and mental traits are also influenced by pathogen prevalence. Prevalence of infectious diseases is related to IQ, which is a measure of intelligence. Countries and regions with higher prevalence have lower average IQ. Certain personality traits, for example, introversion and openness to new experience are more common under low parasite stress, while the opposite (extraversion, skepticism toward new

experiences) prevail under high parasite stress. In fact, much of the uniqueness humans show in terms of mental and social abilities may arise from the ecological dominance they established by a combination of strong selection of traits that protect against parasites and condition-dependent social values, which relate to local parasite adversity. The condition-dependent social values are simply shifts in social values caused by temporal changes in local parasite stress.

Conclusion

Regional and temporal variations in pathogen prevalence have a great impact on humans and human societies. Degree of parasite stress has been linked to aspects of social life such as democratization, conservatism/liberalism, gender equality, sexual restrictiveness, propriety rights, personality family values, and religiosity. In general, higher risk of disease leads to more closed societies, which prefer local contacts and mating and cherish conservative and traditional values. Low risk of disease promotes interaction with other groups and spreading and is linked to more liberal values and higher within-group variety.

Function of Reproductive Strategy (Kurzban)

Sandeepa Prabhu
JHPIEGO, Agra, India

Synonyms

Breeding; Duplication; Procreation; Producing young; Replication

Definition

Reproduction (or procreation or breeding) is the biological process by which new individual organisms – “offspring” – are produced from their “parents”.

Introduction

The most important strategy in the life of any mammal is to beget offspring and thereby perpetuate the species. Although there is considerable variety of reproductive patterns in nonmammalian vertebrates (Weir and Rowlands 1973), reproductive strategies for the human species have basically remained unaltered. Since *Homo sapiens* first appeared, probably in the valleys of Africa, males have always attempted to pass their genes to the largest feasible number of females. Males select those females capable of providing the best quality of oocytes; females invariably have sought a male capable of providing the best means of survival for herself and her offspring. That means the human sexuality has been essentially reproductive in nature, although over the period of time it began to lose fundamental purpose in the cultural evolution of the species. There have been certain major revolutions in the twentieth century. First, with the availability of contraception, sex without the intension of reproduction became a reality; then, with the advancement in assisted reproduction technology, humans have reproduced without intercourse; finally, very recently, women have begun to reproduce beyond the reproductive age. Additional strategies will, no doubt, soon be available, although we cannot as yet clearly see whether, or when, reproduction without sex and gametes, or in vitro gestations, will become available. (Benagiano 2012).

Studies have shown a variety of patterns in sexual desires. Evolutionary psychologists argue that ancestral men who possessed a desire for multiple short-term sex partners, to the extent that they were capable of attracting them, would have left more descendants than men without such a desire. However ancestral women, unlike men, have maximized reproductive success by mating with as many partners as possible, but they preferred to mate with those men who were most able and willing to invest themselves in their offspring. However they have evolved to show sexuality in a bid to compete to get resources from potential men.

One classic study by Clark and Hatfield (1989) found that when college students were interviewed on campus and asked if they wanted to “go to bed” with the opposite sex partner, 75% of the men said yes while 0% percent of the women said yes. There is also an evidence which indicates that across cultures men report a greater willingness to casual sex (Schmitt 2005). A larger desired number of sexual partners (Schmitt (2005) and a greater desire to have sex sooner in a relationship (Schmitt 2005). These sex differences have been shown to be reliable across various studies and methodologies (Baumeister et al. 2001; Oliver and Hyde 1993). However, there is some controversy as to the scope and interpretation of these sex differences (Conley et al. 2011; Schmitt et al. 2012).

There is also evidence that men have a strong desire for casual sex, unlike women. Men are often considered as wanting many opposite sexual partners to increase reproductive success (Flanagan 2012). Evolutionary mechanisms for short-term mating, as well as mate-guarding behaviors and sexual jealousy are evident today. Sexual relations with multiple partners became a recurrent adaptive problem (Buss and Shackelford 1997). The willingness of modern-day men to have sex with an attractive opposite sex partner (Clark and Hatfield 1989) and the prevalence of extramarital affairs in similar cross-cultural are evidence of an ancestral sexual behavior in which polygamous mating strategies were adopted (Buss 1994). However, there is an argument that monogamy has been used to control human female sexual behavior and human female sex drive is not lower than the human male (Smith, Emily Esfahani 2013).

Some of the predictions by evolutionary psychologists stated that when compared to women, men place a greater value on youth and physical attractiveness. The sexual behaviors of youth are associated with reproductive value, features, and physical attractiveness that men usually find in women. These features are thought to signal health and fertility (Buss and Schmitt 1993). In comparison, men who mated with women who are healthy, fertile, and reproductively valuable have

left more descendants than other men who did not, which is being the reason for decline in the reproductive values in women than men with the age since they could not exhibit as strong of a preference for youth in a mate. It is also speculated that women are more attracted to ambition and social status in men, as they associate these characteristics with men's access to resources. Women who mated with men who are capable of having greater access to resources have left more descendants than women who did not mate preferably. These predictions have been tested by evolutionary psychologists across the cultures. Some sex differences in mate preferences may be attenuated by national levels of gender equity and gender empowerment (Eagly and Wood 1999). The specific role that culture plays in modulating sex differences in mate preferences is subject to debate (Gangestad et al. 2006; Schmitt 2011). It is interesting to know that there have been cultural variations in mate preference. Finding a mate with resources becomes less of a priority, and a mate with domestic skills is more important. This is due to women's access to resources varies between cultures, so does mate preference. (Gangestad et al. 2006).

Conclusion

Though human sexual intentions are fundamentally reproductive in nature, due to cultural evolution there have been tremendous changes happening. The reproductive strategies have become multifactorial. Sexual desires and preferences have shown a diversified pattern across cultures. Men and women have been following variety of reproductive strategies based on the resources available to nurture their young ones.

Function Versus Capability

Yiming Qian

The Pennsylvania State University, State College, PA, USA

Synonyms

Biological function; By-products; Identifying adaptive functions; Random effects

Definition

Function	what a biological organization or physical object was designed to do
Capability	all that a biological organization or physical object is able to do, including its designed functions as well as by-products

Introduction

In the memory studies, the capacity of memory has a long history. Until the introduction of modern evolutionary biology into psychology, researchers began to emphasize the origins and nature of memory systems, that is, what the memory system was designed to do (Klein et al. 2002). Knowing the functional design of memory systems helps in figuring out its components and explaining why they exist.

The Capabilities of Memory Systems

The capabilities of memory systems have been studied for almost a century (Klein et al. 2002).

For example, the working memory integrates and infers information to solve current problems (Baddeley 1992), whereas long-term memory helps in planning for the future (Altgassen et al. 2015), making decision (Lynch 1991), acquiring language, and developing relationships with others and personal identity (Klein et al. 2002; Tulving 1985). There are few flaws in memory systems, such as false memory and forgetting. It indicates various capabilities of memory systems are not equally weighted. Finding what is the priority of all these capabilities of a system may give researchers an insight into the designed function of memory.

The Functions of Memory Systems

A biological organization can serve various purposes, but many of them are by-products (Gould and Lewontin 1979; Williams 1966). As most memory systems deal with a great variety of problems, it is a challenge for scientists to identify their designed function. George C. Williams (1966) in his book *Adaptation and Natural Selection: A Critique of Some Current Evolutionary Thought* summarized, “An effect should not be called a function unless it is clearly produced by design and not by chance.” To discriminate the functions of a biological organization from its by-products, Klein and his colleagues (2002) set criterion of whether this capability is well designed to solve adaptive problems.

However, any functionalist claim in psychology cannot be grounded without an evolutionary perspective. It is very difficult to make the distinction between functions and their by-products in a functional organization. It is important to note that multiple memory systems have been shaped and constructed by the prior natural selection in the evolutionary process (Klein et al. 2002; Sherry and Schacter 1987). Besides the products of natural selection, the stochastic process of evolution also introduced noise into functional designs (Klein et al. 2002). In the late twentieth century, researchers attempted to distinguish the original design of memory systems and the functional product of evolved adaptations by investigating

what adaptive problems a memory system was designed to solve (Klein et al. 2002; Nadel 1994; Sherry and Schacter 1987).

Generally, researchers argue that memory systems are designed to take advantage of previous information to solve adaptive problems posed by the environment, such as offspring, the locations of food, and environmental threat (Klein et al. 2002). For example, memory systems allow birds to recognize and keep potential predators away from their nest and young, remember the winners and losers of a previous contest to reduce the cost of competition, exploit efficiently the available food resources, and associate flavor or appearance of food with illness (Sherry and Schacter 1987). Moreover, multiple memory systems have distinct functions. In 1987, Sherry and Schacter highlighted that the evolution causes the functional specialization of multiple memory systems. A memory system is designed and evolved to solve the demands posed by a new environmental problem, which the other system cannot handle. Thus, memory research needs to identify the functions of each memory system, the components of these functional organizations, as well as the causal relationship between the functions and their structures. Besides, knowing the functions of memory systems can help to find the other nonfunctional capacities.

Conclusion

Any system designed to solve a problem has its well-designed organization and structure to achieve a particular goal. Memory systems use acquired information to facilitate present and future behaviors. A conceptual distinction between functions and capabilities plays a vital role in advancing our understanding of the functional design and structure of memory systems.

Introduction

In the last decade, some researchers have begun reconceptualizing Abraham Maslow's classic 1943 hierarchical model of human motivations to reflect recent insights from the fields of psychology, anthropology, and evolutionary biology (e.g., Kenrick et al. 2010a). Since that reconceptualization, this line of research has followed three trends: (1) activating different motives to explore their effects, (2) examining individual differences in the fundamental motives, and (3) looking at how fundamental motives apply cross-nationally.

Conceptualizing the Fundamental Motives Framework

The fundamental motives were conceptualized as an update to Maslow's classic hierarchical models of human needs, which included separate needs related to one's physiology, safety, esteem, and self-actualization, respectively (Maslow 1943). From this classic work, the fundamental motives framework retains the idea that motives are discrete (i.e., reflect different drives) and hierarchical (i.e., that they reflect the order of cognitive priorities if particular needs are deprived as well as the order of development across the life span). In addition, the new framework retains the idea that motives can be activated without conscious awareness (Kenrick et al. 2010a).

The fundamental motives framework also leverages insights from evolutionary theory to somewhat retool which motives are contained in its hierarchy. First, it incorporates the idea of *inclusive fitness*, namely, the insight that over time, particular traits have been selected in part because they have consistently been successful at helping organisms pass on their genes either via successful reproduction or the care of

Fundamental Motives

Adi Wiesel
Arizona State University,

Synonyms

[Fundamental motives framework](#); [Fundamental social motives](#)

Definition

The fundamental motives refer to a hierarchical set of discrete human motivations, separated in terms of their evolutionary function and organized in a pyramid based on the order in which they develop across the life span and the order in which they are prioritized when triggered. Specifically, the fundamental motives include

kin with shared genes. By this logic, human motivations are likely to account for persistent selection pressures that may have affected humans' ability to successfully pass on their genes. Importantly, successful mating and kin care in humans require that several additional goals be accomplished: they must successfully gather resources as well as create and maintain the social networks and status required to successfully recruit and retain mates. Accordingly, the fundamental motives framework incorporates such goals in its pyramid of human motives, which include, in order of cognitive and developmental priority, *immediate physiological needs*, such as warmth and sustenance, *self-protection*, *affiliation*, *status/esteem*, *mate acquisition*, *mate retention*, and *parenting* (Kenrick et al. 2010a; Schaller et al. 2017). Notably, and as alluded to above, people do not have to be consciously aware of that they are pursuing a given motive—indeed, some recent work suggests that the things people do when they are feeling most self-actualized are typically linked to status-seeking motives (Krems et al. 2017).

A second evolutionary insight that the fundamental motives framework incorporates is *life history theory*. Specifically, it emphasizes the notion that organisms experience a fundamental tradeoff in the time and resources they invest in one of three things: their bodies (i.e., somatic effort), mating, and parenting. So too do these trade-offs manifest differently across the life span; whereas young children concern themselves with meeting their physical needs, people later begin to prioritize reproductive, mate-retentive, and kin care goals. Later goals sometimes build on successful completion of earlier goals; for example, to successfully recruit a mate, one needs to be able to socially affiliate in order to attain the status needed to recruit a mate. Thus, in terms of life history, the motives lower in the hierarchy are more aligned with somatic efforts, and the motives higher in the hierarchy are aligned with mating and parenting efforts (Schaller et al. 2017). Notably, people don't "grow out of" lower levels of motives, they simply add on more of them; if a stimulus triggers a lower motivation, people are still equipped to

respond to it (Kenrick et al. 2010a; Schaller et al. 2017).

There are several lines of research associated with the fundamental motives framework. These involve (1) activating different motives to explore their effects, (2) examining individual differences in the fundamental motives, and (3) looking at how fundamental motives apply cross-nationally.

Activating Fundamental Motives to Explore their Effects

One line of work in the fundamental motives tradition has focused on examining the effects of activating different fundamental motives on various aspects of social cognition and decision-making. Studies in this line of research temporarily prime, or activate, different motives, often by using film clips (e.g., Maner et al. 2005) or evocative vignettes (e.g., Griskevicius et al. 2006, 2009, 2010) to examine their effects. For example, whereas, a story about a late-night break-in might be used to elicit a self-protection motive, a story about a vacation where someone meets a romantic interest might be used to elicit a mating motive (Griskevicius et al. 2006), and a story about a competitive job environment might be used to activate a status desire motive (Griskevicius et al. 2009, 2010).

Work in the fundamental motives priming tradition has suggested that different motives have different downstream consequences. For example, when a self-protection motivation is activated, people tend to conform more (Griskevicius et al. 2006) and perceive more anger on outgroup (but not ingroup) faces (Maner et al. 2005; Kenrick et al. 2010b). By contrast, other work has suggested that when a status desire motive is activated, people are more likely to select expensive versus inexpensive green products (Griskevicius et al. 2010).

Some work in this tradition has also suggested both person and situation-level moderators of the downstream consequences of specific fundamental motives. For example, sex has often been identified as a moderator of the effects of mating and status motive primes. Mating motive primes lead men, but not women, to perceive sexual arousal in attractive opposite sex faces (Maner

et al. 2005). And, whereas status desire motives have been found to make women more indirectly aggressive and men more directly aggressive, this finding only holds for men under a mating motive prime when they are in the presence of other men (Griskevicius et al. 2009).

Examining Individual Differences in the Fundamental Motives

Another approach has moved from examining state-level differences in fundamental motives to exploring trait-level differences in these motives. This work has resulted in the creation and validation of a 66-item inventory which covers individual differences in fundamental motives across the domains of self-protection, disease avoidance, affiliation, status, mate seeking, mate retention, and kin care (Neel et al. 2016). This work has suggested that some of these motives break down into further subcomponents when considered at the trait level. Specifically, affiliation motivations consist of three distinct subcomponents, group affiliation, exclusion concern, and independence; mate retention consists of two subcomponents, general mate retention and concerns over breaking up; and kin care also consists of two subcomponents, care for one's family more generally and care for one's offspring in particular.

This work has also begun to explore the personality and behavioral correlates of individual differences in the fundamental motives. For instance, Neel and colleagues examined some of the relations between the fundamental social motives and other individual difference measures, such as belief in a dangerous world and the Big Five Personality Inventory. They found that whereas motives for self-protection and disease avoidance were related to constructs such as belief in a dangerous world, motives for affiliation group and kin care family were strongly related to agreeableness from the Big Five. Participants high on different fundamental motives also reported different kinds of behaviors. For example, people higher on a self-protection motive were more likely to have reported having taken a self-defense class in the last year, whereas people higher on a kin care family motive were

more likely to have taken care of a young relative in the last year (Neel et al. 2016).

Looking at how Fundamental Motives Apply Cross-Nationally

Although prior research on individual differences across the fundamental motives has primarily been conducted using American samples (Neel et al. 2016), recently, researchers have become interested in how individual differences in the fundamental motives apply in cross-national contexts, as well. For example, in one study utilizing data from 27 different countries, people consistently viewed familial goals, such as kin care and mate retention, as among the most important motives, and mate-seeking goals as among the least important motives (Ko et al. *in press*). Moreover, the familial goals were linked with higher levels of well-being, whereas mate-seeking goals were linked with increased depression and anxiety (Ko et al. *in press*). This kind of cross-cultural work, and work which focuses on mate retention and kin care motives in particular, reflects an active area of study.

Conclusion

The fundamental motives framework updates more classic, hierarchical models of human motivations to include insights from evolutionary theory. More specifically, the fundamental motives constitute a hierarchical set of discrete needs which are organized both in terms of their developmental and cognitive priority; however, these motives do not fully replace one another across the life span. The motives consist of *immediate physiological needs*, such as sustenance and warmth, *self-protection*, *affiliation*, *status/esteem*, *mate acquisition*, *mate retention*, and *parenting* (Kenrick et al. 2010a; Schaller et al. 2017). Typically, experimental work has examined how activating different motives at the state level can have differential consequences for outcomes like cognition (e.g., Kenrick et al. 2010b) and behavior (e.g., Griskevicius et al. 2010). More recent work has also expanded into considering more trait-level individual differences in

the fundamental motives, both in US (Neel et al. 2016) and cross-national (Ko et al. *in press*) samples, and reflects an area of relatively active research.

Definition

Trade-off: Allocation of a finite energetic budget toward two or more competing phenotypic traits
Life history theory: A mid-level evolutionary theory that investigates between and within species variation in size at birth, age at weaning, age at

sexual maturity, age at first reproduction, adult size, senescence, and intergenerational birth interval and number of offspring produced.

Introduction

Life history theory is a branch of evolutionary biology that combines information about mortality, reproduction, growth, and development (Chisholm et al. 1993; Stearns 1992) with the intent to understand variation in size at birth, growth rate, age and size at sexual maturity, parity, the number of offspring produced, life span, and mortality rates across species (Stearns 1992, 2000). For example, some species grow slowly, reach a very large adult size, reproduce late and few times during their life, produce few offspring that they care for a long period, and have longer lifespans. Other species are characterized by exactly the opposite, a small adult size, early reproduction, large litter size, and short life span. Evolutionary biologists interpret these correlations across species as an indication that these traits are distributed on a slow to fast life history continuum and use different theoretical models such as *r/K* selection (MacArthur and Wilson 1976; Pianka 1970) and bet-hedging (Promislow and Harvey 1990) to investigate them. From these models and the empirical studies that followed from them, it is apparent that organisms make strategic reproductive decisions depending on the ecological factors they experience, which are linked to mortality rates, and that these decisions have costs that can influence the organism future reproduction and risk of mortality. Obviously these decisions are not the result of conscious thought but instead they are the result of a complex combination of genetic variation and phenotypic plasticity resulting from environmental conditions (Ellis et al. 2009).

One of the most important tenets of life history theory is that time and energy are limited factors that must be optimally allocated toward competing life functions, such as growth, survival, and reproduction. Everything else being equal, organisms should have been selected to maximize their

metabolic and the intake of material resources per units of time (Pianka 1970) or, in other words, organisms did not evolve to acquire an infinite amount of energy at no costs. Because of this limitation, the energy that an organism directs toward a specific life function, let's say growth, cannot be allocated to reproduction. Likewise, the energy allocated toward reproduction cannot be used also to improve survivability, for example, by investing it toward strengthening the immune system. In fact, one of the most intriguing proposals of life history theory is that a hormonal biomarker of reproductive status such as testosterone could negatively influence the effectiveness of the immune system in fighting infections (Roney 2016).

Biologists consider that individual organisms engage in two types of efforts during their lifetime: somatic and reproductive efforts. Somatic effort is represented by the time and energy allocated to systems important for growth and survival. Reproductive effort is represented by the time and energy allocated to mating and parenting effort (Alexander 1987). The decisions that organisms face when allocating energy between these different efforts are defined as life history trade-offs and these trade-offs shape intra-individual and intergenerational life history variables such as when to reproduce, how frequently, how many offspring, how much investment should go toward each of them and lifespan. There are three fundamental trade-offs in life history theory: current versus future reproduction, quantity versus quality of offspring, and mating versus parenting effort (Kaplan and Gangestad 2005; Del Giudice et al. 2015).

Fundamental Trade-Offs in Life History Theory

Current versus future reproduction. This is probably the most important life history trade-off (Ellis et al. 2009). If current conditions are not optimal for successfully growing new offspring, investing in reproduction would certainly be a waste of resources with intergenerational and individual

costs. Intergenerational costs are represented by the likelihood that offspring will not survive to reproduce, thus decreasing inclusive fitness. Individual costs are represented by the impossibility of reallocating the invested resources toward future reproduction, with the extreme case in which current costs are so high that the mother will not survive to the next reproductive season. For example, breastfeeding is energetically expensive and resources allocated in lactation cannot be allocated in fat storage. A nursing red deer may face higher risk of mortality following weaning of her calves if winter conditions are harsh (Clutton-Brock et al. 1982). In such circumstance, natural selection should favor organisms that give up current reproduction while investing in somatic effort. However, if the prospective for future reproduction is very small, for example, because of high mortality risk from environmental factors, it may pay to invest everything in current reproduction. The current versus future reproduction trade-off is very important in shaping the relationship between somatic and reproductive effort and is strongly linked to life-expectancy, quality versus quantity of offspring, and mating versus parenting effort (Caudell and Quinlan 2012; Ellis et al. 2009).

For a developing organism, the most fundamental decision is when to begin to reproduce, that is, at what age should be reproductively mature. Everything else being equal, a further investment in growth and survivability will postpone the age of sexual maturity. The benefits of this type of strategy is that resources can be allocated toward growth of traits that are advantageous for intra- and intersexual selection: larger size, more elaborated phenotypes that are important for courtship, and, especially for humans, an increase in embodied capital (Kaplan et al. 2003) that allows the learning of sociocultural rules and the exploitation of ecological resources in ways that provide intrasexual competitive advantages. However, a serious cost of this strategy is the risk of dying before reaching sexual maturity or to reach sexual maturity when there is not much time left to be reproductively successful. On the contrary, reproducing at an earlier age can increase life-long fertility, but it is unlikely that

this strategy will translate in higher fitness per number of offspring produced (Gillespie et al. 2008).

Hence, life expectancy plays an important role in shaping the trade-off between current and future reproduction and the resulting life history traits. Life expectancy depends partially on mortality risk originating from extrinsic factors, that is, from unpredictable events that are ecology dependent such as the levels of predation, violence, and morbidity (Ellis et al. 2009). When mortality risk is low, we observe that species tend to shift toward the slow end of the slow to fast life history continuum. The contrary is expected when mortality rates caused by extrinsic factors are high. Several scholars of life history theory (Chisholm et al. 1993; Del Giudice 2009; Ellis et al. 2009; Quinlan 2007) hypothesized that children can use the level of parental support experienced during the first 5–7 years of life (Belsky et al. 1991) to gather information about the harshness (levels of morbidity and mortality) of the future adult environment and, accordingly, adjust their reproductive strategies.

This model has been used by many developmental evolutionary psychologist and evolutionary anthropologists to explain, for example, variance in girls' pubertal development and age at first reproduction across different socioeconomic statuses and ecologies. For example, Sheppard and collaborators (Sheppard et al. 2016) reported that in a high socioeconomic status (SES) historical population from the United Kingdom girls from lower SES and with crowded housing tended to give birth at an earlier age and had an overall higher fertility. Similar results have been reported for other industrial populations (Nettle 2010). Likewise, less supportive parenting during early childhood predicts earlier adrenarche and sexual maturity in girls (Ellis and Essex 2007).

Plasticity in age at sexual maturity depends on different types of environmental cues which, at first sight, may look contradictory. For example, chronic stress from lack of nutritional status during early childhood results in postponed pubertal development while, as previously described, early stress resulting from lower parental support

results in an earlier reproductive development (Ellis 2004). Hence, different types of stressors may have different effects on life history trajectories and Ellis and collaborators proposed a model in which, in harsh environments, parenting sensitivity and provisioning plays the most important role in determining life history reproductive strategies (Ellis et al. 2009).

Quantity versus quality of offspring. Since parents have limited resources that can be invested in reproduction, for every additional offspring produced the amount of resources that can be allocated to each decreases. Put it simply, the larger is the investment in number of offspring, the smallest is the investment per offspring. Evolutionary biologists found that this is a very successful reproductive strategy when ecological conditions are unpredictable and there is a high adult mortality rate (Stearns 1976). In these conditions, from a parent's fitness perspective, it pays to produce many small size offspring (size is generally a proxy for smaller parental investment) where at least one of them may successfully reproduce as an adult. On the contrary, when the ecology is stable, juvenile mortality is comparatively higher than adult mortality, and the adult socioecology requires highly competitive adults, as it pays to increase parental effort, that is, to invest in less offspring but of higher quality. In this way, parental investment increases the chances of survival of the few offspring through the juvenile period, and it increases their competitive advantage once they reach adulthood (Del Giudice et al. 2015; Ellis et al. 2009).

As a species, humans stand in the slow end of the fast-slow continuum of life history strategies, with mothers that give birth to one child and rarely to twins or triplets. However, the trade-off between quantity and quality of offspring in relation to ecological uncertainty can still be observed. For example, in a population from rural Ghana which experiences high mortality rates, fertility was very high, and for each additional child in a family there was more than a 2% decrease in offspring survival (Meij et al. 2009). A similar result was reported by Gillespie and collaborators (Gillespie et al. 2008)

who used historical census records representative of a pre-industrial population of Northern Europe. In their study, Gillespie and collaborators reported that women from lower SES had higher fertility but lower fitness compared to women of higher SES since a smaller proportion of their children lived long enough to reproduce. Yet, given their socioeconomic status, from a purely evolutionary biological perspective, they made the best out of a bad situation.

Mating versus parenting effort. The trade-off between mating and parenting effort is closely related to both current versus future reproduction and offspring quantity versus quality trade-offs. For species that reproduce sexually mate searching and copulation have substantial risk, time, and energy costs (Del Giudice et al. 2015; Kaplan and Gangestad 2005). For a parent the investment in current offspring reduces the time and energy required to produce and/or invest in other offspring (it decreases fertility), while investing in further fertility reduces the investment in current offspring. This trade-off results in reproductive conflict of interest between parents which, in the majority of vertebrate species and for reasons explained by sexual selection theory, resolve with females tending to invest more in parenting effort and males in mating effort.

Life history theory predicts that sex specific and individual differences in the preference for mating versus parenting efforts depend on the levels of mortality risk and morbidity. Generally speaking, the sex that experiences the highest mortality is the one that invests the most in phenotypes and behaviors that increase mating competition (Del Giudice et al. 2015). Compared to other mammals, human males provide high paternal investment (Geary 2000) and, as for other biparental species, women mate choice can select for males that provide support for their offspring, a strategy that would increase female fertility and offspring survival.

Life history theory provided an important model for the study of variation in the proportion of maternal and paternal efforts across different human populations. For example, Quinlan

(2007) showed that in harsh environments characterized by famine, warfare, and high pathogen loads, maternal and paternal investment are lower, with mother terminating breastfeeding at earlier ages. When ecological conditions are harsh, the lower level of parental investment appears to be a consequence of the limited benefits that the parent would gain by investing further energy and time toward children with poor survival expectations. In turn, children can use the levels of their parent's investment to develop behavioral and psychological reproductive strategies that are functional for dealing with that specific ecology (Ellis et al. 2009). The prediction of life history theory is that if the future environment is harsh and little parental support is received then, through the development of specific attachment styles, children will tend to follow a mating effort strategy which is characteristic of a fast life history (Chisholm et al. 1993; Del Giudice 2009; Ellis et al. 2009). Behaviorally this strategy is characterized by unrestricted sociosexuality, a decreased ability to delay gratification, higher risk taking, aggressive, and competitive behaviors.

In this regard, life history theory has been used by psychologists and evolutionary anthropologists to explain the relationship between life expectancy and risky behaviors that place youth at higher risk of mortality and morbidity (Wilson and Daly 1997; Ellis et al. 2012). For example, several studies looked at behavioral and psychological correlates of mating effort, family structure, and socioeconomic status and showed that children growing up in a family with a single mother or a stepfather have an earlier sexual debut, abuse illicit substances, and report higher rates of violence (Copping et al. 2013; Sheppard et al. 2014) and colleagues (Kruger et al., 2008) showed that in a population of youth from a blue collar city of the United States, kids from poorer and harsher neighborhoods scored higher in aggression and illegal resources acquisition and that the relationship between ecology and risky behaviors is mediated by a present oriented time preference. Another study showed that subjects from lower SES prompted

with cues of a shorter life expectancy have preference for behaviors indicative of high mating effort (Griskevicius et al. 2011). Likewise, being exposed to a stressful environment at an early age influences youth's preferences for unrestricted sociosexuality, aggression, and delinquency (Simpson et al. 2012).

Conclusion

Life history theory is a mid-level analysis theory that historically has been used by evolutionary biologists to understand differences in functions and structures between species and individuals. The idea of trade-offs between competing traits and the costs that these tradeoffs have for the organism's fitness represent the core of life history theory. There are three types of fundamental trade-offs, each concerned with how an organism should, from an evolutionary point of view, optimally invest its limited metabolic budget: (1) when and how much to invest in current or future reproduction; (2) Investing in more offspring of lower quality or in few of higher quality; and (3) when and how much to invest in mating effort or parenting effort.

In recent years, the use of life history trade-offs by evolutionary psychologists and anthropologists has been successful in modeling variation in human parenting styles, pubertal development, trends in fertility, and also more psychological variables such as time perspective, sociosexuality, and risky behaviors. All of these factors have broad health and economic impacts on modern societies, and very likely, the use of more sophisticated approaches that aim at identify more subtle subtypes of life history trade-offs (Del Giudice et al. 2015; Nettle et al. 2013) will provide a powerful tool that makes very exciting the future study of psychopathology, biomedicine, and demographics.

Definition

The science of strategy studied using mathematical, interdependent, logic choice games between two or more players.

Introduction

In essence, *game theory* is the science of strategy. Research in this field aims to determine the action or set of actions that players should logically take to secure the best outcomes for themselves. The set of conditions and rules dictating players' choice of actions, and consequences of those actions are referred to as games. There are numerous specific games, but they all share the common qualities of *interdependence*, in that the outcome for each player depends on the chosen actions of other players, and *conflict*, in that there is the potential for different gains or losses between players. Thus, decisions in games are different from decisions made in a "neutral" context without other players (such as with inanimate objects), and as in a neutral context, there is no dependence linked to the chosen actions.

"Games" in Game Theory

There are three broad categories of games in relation to outcome: (1) zero-sum games, (2) positive-sum games, and (3) negative-sum games. *Zero-sum* games are where one player's gain always causes another player's loss meaning that the interests of the players conflict totally. A classic example of a zero-sum game is *Rock, Paper, Scissors*. *Positive-sum* games are where there is the option for mutual gain, and conflict arises between the division of gain or sometimes options

alongside mutual gain or loss for the other player. Lastly, *negative-sum* games are where there is similarly the potential for mutual loss as well as some conflict on the degree of loss.

Game theory was first coined by mathematician John von Neumann (who was one of the conceptual inventors of the stored-program digital computer and who was involved in the Manhattan Project). Neumann originally focused on zero-sum games (games of total conflict); if there was cooperation, it was typically “yoked” (i.e., players were supposed to choose actions together). Most recent research typically focuses on games that are neither pure conflict nor purely cooperative. In other words, researchers now use games where the players choose actions separately, but they include consequences for others, yielding both a competitive and cooperative component.

A player in a game must recognize that they are interacting with other players. At the core of these games is the interaction and interdependence of the player’s strategies. There are two general types of interdependence: sequential and simultaneous. In sequential interdependence games, the players make choices and act in sequence, aware of the other player’s (or players’) previous actions, whereas in simultaneous games, players act at the same time, aware of the other player’s (or players’) actions. Note that simultaneous games can be played in sequence (i.e., multiple rounds), making the overall game a hybrid of the two. In a sequential game, players need to consider how the other players will respond to each choice, and how they will respond to other player’s choices. That is, a player needs to anticipate what consequences choices will lead to in relation to how it will influence the other player (s) and use this information to decide on the best option. Therefore, games require mind perception and person perception (Epley and Waytz 2010).

Some examples of common games in game theory are (1) the *Bargaining Game*; (2) the *Ultimatum Game*; (4) the *Public Goods Game*; and (5) the *Hawk-Dove game*. The *Bargaining Game* is a simple two-player interaction used to model bargaining scenarios. Two players demand a portion of some good (e.g., an amount of money) and both players get their request if the total amount

requested by the players is less than the total amount available, but, if not, neither player gets their request. Similarly, the *Ultimatum Game* is a simple two-player interaction where each player takes a different role; the “proposer” player determines how to split a set amount of some good (e.g., an amount of money) between the players, and then the “responder” player decides whether to accept or reject the offer. If the offer is rejected, neither player receives any of the good. In the *Public Goods Game*, participants are given an amount of some goods (e.g., tokens) and covertly choose how much of this good to put into a public pot and how much to keep. After each player has done so, the public goods are multiplied by some factor and evenly divided among players. The *Prisoner’s Dilemma* game involves a simultaneous choice (i.e., each player must make the choice without knowing what the other will do) between two players to either cooperate or defect. In this game, defection yields a higher payoff than cooperation when paired with a cooperate choice from the other party, but, if both defect, both do worse than if both had cooperated. In addition, the cost of being defected on after cooperating is still greater (see Prisoner’s Dilemma entry for more detail). The *Hawk-Dove game* is a simple two-player interaction used to model conflict vs. sharing of a resource. It is similar to the Prisoner’s Dilemma except the cost of both players choosing conflict (equivalent to defecting in the Prisoner’s Dilemma) is significantly greater.

In solving these games, if one player’s best choice is the same no matter what the other player(s) do, it is called a “dominant strategy,” and if a player’s strategy uniformly yields a bad outcome, it is called a “dominated strategy.” Through active research or simulations, game theorists are typically concerned with identifying dominant strategies and eliminating dominated ones. Often, the dominant strategy is dependent on whether the game is one-shot (only played once per game partner) or round based (played multiple times between the same players in sequence). For example, in a one-shot ultimatum game, the responder should choose to accept the absolute minimum amount from the split as anything is better than nothing. However, in multiple

rounds, this strategy can be exploited by the proposer to repeatedly give the receiver the bare minimum share. Therefore, it can be more advantageous for the responder to “stick to their guns” at a more even split (or even a split in their favor) over multiple games, forcing the proposer to be more fair (or even concede the larger portion) to the responder to avoid having offers thwarted, and thus receiving no share. Also see “The Evolution of Cooperation” entry, for the dominant strategy in multiple Prisoner’s Dilemma games, or Axelrod (Axelrod and Hamilton 1981; 1984).

Conclusion

Game theory is the science of strategy studied using mathematical, interdependent, logic choice games between two or more players. The set of conditions and rules dictating players’ choice of actions, and consequences of those actions are referred to as games. The various specific games all share the common qualities of interdependence, in that the outcome for each player depends on the chosen actions of other player(s), and conflict, in that there is the potential for different gains or losses between players.

Definition

Game theory is the mathematical analysis of interdependent systems composed of fitness- or utility-maximizing “actors” (e.g., humans, animals, genes, or viruses) whose success depends on the strategies of others.

Introduction

Game theory is a useful tool for understanding interdependent systems. It is a mathematical description of how individuals should behave in contexts in which the outcomes of their actions depend on the behavior of other individuals. Game theory has been applied to topics as varied as climate change negotiations (Helm et al. 2012), the evolution of cooperation (Nowak 2006b), and viral population dynamics (Turner and Chao 1999). Game theory makes sense of different “strategies” and “payoffs” by using the

mathematical logic of each individual agent's perspective. Game theory was first used to model rational, conscious actions by humans in strategic settings; however, its usefulness now extends well beyond the realm of decision-making. The interaction between "strategies" could involve individuals making choices on a playing field, phenotypic traits occurring at different frequencies within a population, or genes within a body fighting to be passed on. In all of these cases, a successful "strategy" – choice, trait, or gene – depends on what others are doing (Maynard Smith 1982). Traits of interest to evolutionary psychologists are highly suitable to game theoretic approaches, because they so often depend on interactions between individuals.

Game theory is of fundamental importance to evolutionary psychology in four domains. First, traditional game theory played a role in the historical transition of psychology away from behaviorism and Freudian thought and toward experimentalism, microeconomic methodology, and evolutionary psychology (Gintis 2009). Second, game theory provides a rigorous methodology for documenting human decision-making and understanding the evolutionary basis of seemingly "irrational" human behavior. Third, evolutionary game theory yields new insights into the development and maintenance of complicated and seemingly paradoxical traits such as cooperation, long-term partnership, and altruism. Finally, many small, self-interested agents compete ("play games!") within our bodies – selfish genes, microbes, viruses, and more – with demonstrable impacts on our psychology and behavior. Because of its contributions in these four areas, game theory is a valuable tool in our effort to model and understand our evolved brains.

Game Theory

"The world" is something like a great chess game being played by the Gods, and we are observers of the game. . . . If you play chess you must know that it is easy to learn all the rules, and yet it is often very hard to select the best move or to understand why a player moves as he does. So it is in nature, only much more so – Richard Feynman.

Historical Background

Game theory, like probability theory, arose from literal games. Probability can model and interpret dice rolls and games of chance, but game theory models poker and chess – games that depend at least in part on uncertainty about other players' decisions (Sigmund 1993). John von Neumann and Oskar Morgenstern are the true fathers of game theory, but their brilliant twentieth century contributions did not occur in a vacuum; more than 200 years before their work, the first game-theoretic (i.e., mathematical) analysis of strategy was proposed. In 1713, Francis Waldegrave described a mathematical "mixed strategy" solution to the two-person card game *Le Her* in a letter to probabilist Pierre-Remond de Montmort. Montmort, in turn, passed the solution on to the mathematician Nicolaus Bernoulli. (This ongoing web of correspondence is most famous for its analysis of the St. Petersburg Paradox, a game with mathematically infinite "expected value" but paradoxically low subjective value to humans. This paradox is an early example of our growing awareness that humans are not perfectly rational actors in a classical, economic sense.) Waldegrave analyzed which strategy would give a player the best odds of winning, taking into account card distributions as well as the opponent's strategy. A more detailed discussion of *Le Her* and Waldegrave's work is beyond the scope of this entry; it is sufficient to note that this was apparently the first instance of a mathematical treatment of human strategy.

Games such as Chess, *le Her*, and Go inspired much verbal and some brief mathematical treatment of strategy for several centuries. But game theory in its true, mathematical form is the invention of John von Neumann and Oskar Morgenstern, with significant fundamental contributions from John Nash (among others). (John von Neumann was a genius who made significant and fundamental contributions to multiple fields, from pure mathematics to physics, computer science, and statistics. His impact beyond the invention of game theory is not always fully appreciated; Nash was admitted to Princeton as a PhD student with a three-sentence letter of

reference concluding “He is a mathematical genius.” He went on to receive the Nobel Prize for a single-page paper.)

In 1928, von Neumann wrote a seminal paper which founded the modern form of game theory (von Neumann 1928). In the 1940s, von Neumann and Morgenstern wrote a definitive treatise on game theory, entitled *The Theory of Games and Economic Behaviour* (von Neumann and Morgenstern 1944). They described games in formal mathematical detail and proposed rigorous methods of assessing behavior. In the preface to the first edition, von Neumann and Morgenstern outline their aims as follows: to provide a rigorous analysis of games, as well as sociological and economic problems, that involve “questions of parallel or opposite interest, perfect or imperfect information, free rational decision or chance influences.” (von Neumann and Morgenstern 1944). The pair’s greatest contribution was a formal mathematical treatment of topics characterized by opposing or colluding interests, chance, and varying levels of information availability.

In the middle of the twentieth century, John Nash came onto the scene with fundamental contributions that led to game theory as it is today. He furthered our understanding of what is now known as a Nash equilibrium a “stable state” of a game in which no single participant can gain from unilaterally changing strategy while all other participants’ strategies remain the same. Over the course of game theory’s development, much attention has been given to developing robust “solution concepts,” or predictions about how a game should be played to maximize payoff, against a variety of new introduced complications (such as repeated games, and errors of judgment).

Since the work of these early pioneers, game theory has been employed and expanded upon by economists, political scientists, philosophers, biologists, and mathematicians; it has been the subject matter of many Nobel Prizes and has made significant contributions to multiple fields. In particular, game theory has played an important role in the transformation of psychology over the last 70 years from a field defined by Freudian thought, behaviorism, conditioning, and proximate cause to its current formulation as an

experimental, biological, and mathematically rigorous evolutionary discipline (Gintis 2009). Game theory’s influence began to be felt as early as the 1950s and 1960s, when psychologists began to uncover paradoxes in supposedly rational human thought through experimentation (e.g., Allais 1953); these results – and the emerging widespread interest in game theory (perhaps most notably exemplified by Martin Gardner’s famous “Mathematical Games” column in *Scientific American* from 1957 through 1986.) – soon led psychologists to analyze decision-making via game theoretical experiments. The theories that emerged – e.g., regret theory, hyperbolic discounting, risk aversion, and other modes of discovered “irrationality” – owe a clear intellectual debt to the methodologies and principles of game theory (Gintis 2009).

While psychology was undergoing this experimental revolution, leading biologists and ethologists such as Konrad Lorenz and Niko Tinbergen began to investigate seeming paradoxes between self-interested evolution and cooperative animal behaviors. E. O. Wilson applied interpretations of animal behavior to human behavior in his landmark 1975 book (Wilson 1975), while John Maynard Smith (no relation to John Maynard Keynes, founder of macroeconomics) formalized and described evolutionary game theory as a fundamental new tool of biological analysis (Maynard Smith 1982). In short, game theory has helped provide mathematical rigor and experimentation to the field of psychology and has thus paved the way (with biology) to the development of evolutionary psychology.

Traditional Game Theory

Overview

In its original and simplest form, game theory is an economic tool to model human strategic behavior. It is often used in behavioral economics, experimental economics, decision theory, psychology, economic psychology, and more. When will individuals be selfish? When does it pay to be aggressive, and when does it pay to cooperate? What circumstances give rise to altruism? As

we will see below, many experimental “games” answer these questions in a lab setting, such as the commonly-described games Prisoner’s Dilemma, Hawk-Dove, and more.

A “game” is an interplay of actors, each of whom rationally seeks to maximize her own preferred results (formally defined as her utility). These actors can adopt a number of “strategies,” or methods of engaging with other actors, and, as time goes forward, good strategies are rewarded and bad strategies are punished.

Each person does not know what strategy the others will employ. Eventually the game may result in a stable “solution” – a solution where one best strategy rises to dominance among all the actors, or where the proportion of actors with certain strategies remains constant over time. As we will see later, such stable strategies are not always achievable – consider a game where strategy A beats strategy B, strategy B beats strategy C, and strategy C beats strategy A. Furthermore, there can be “high” and “low” peaks of stability; imagine two adjacent mountain ranges with a valley in between. Human actors seeking to climb as high as possible can only tell whether they are headed up or down; as a result, they may well continue on a path toward a “good” outcome (the lower of the two peaks) without ever catching sight of the “best” outcome. We will discuss evolutionary game theory in detail in section “[Evolutionary Game Theory](#)” below, but for now simply note that evolutionary game theory deals with “actors” that can be individual organisms, single species, or genes and with “strategies” that are quite broadly defined to include not only behaviors but also a wide range of other variables such as phenotypes and proportions of genes in a population.

Types of Strategies and Strategy Sets

Actors can adopt pure or mixed strategies from a strategy set that is continuous or discrete. Pure strategies are individual and consistent for a given actor. In traditional game theory, pure strategies are a single actor’s commitment to act in a single way all the time. A prisoner could always defect (not cooperate), or always cooperate. As we will see in more detail in section “[Evolutionary](#)

[Game Theory](#)” below, single-locus-determined genetic traits, such as hair color (determined by a single gene), are “pure” strategies (in the evolutionary sense).

Mixed strategies involve assigning a probability (sampled from a continuous distribution) to each element of a finite, discrete set of strategies. For example, when choosing from the strategy set “cooperate” or “defect,” an individual could consistently cooperate with others at a 60% rate and defect at a 40% rate. This does *not* require that she knows what others will be doing; it simply means that 60% of the time she encounters another person in a game, she will cooperate, and 40% of the time she will defect.

In game theory, continuous strategy sets can be distinguished from discrete strategy sets. One example of a continuous strategy set would be an investor deciding *when* to sell a stock, because time is continuous. (Since we can only measure time at discrete moments, it is only an approximation to say time is continuous.) She could select any time within brackets, with a probability distribution over the range of times. Many evolutionary “strategies,” or “traits,” are continuous, such as height, weight, brightness of color, or neuron density.

In contrast, discrete strategy sets offer well-defined, nonoverlapping options – such as the potential behaviors “cooperate” or “defect,” or a gene coding for blue eyes versus brown eyes.

Types of Games

Games can be symmetric or asymmetric. The former involves players with access to the same set of strategies: for example, in a symmetric hawk-dove game, each individual can choose to act as a hawk or a dove. Hawks in this game are aggressive: they attack whomever they encounter in order to try to claim the whole food resource. Hawks receive a bonanza if they encounter a pushover Dove, but self-destruct through fighting if they encounter another Hawk. Doves are docile; they either accept defeat (and a small payoff) if they encounter a Hawk or split the reward if they encounter another Dove. In typical formulations of the game, each actor will adopt a consistent strategy to be either a Hawk (H) or a Dove (D) for

all of that actor's encounters (in most formulations of the game, actors do not know which strategy their opponents will choose). The optimal strategy ultimately depends on the relative payoffs of the four possible types of encounter (H-H, H-D, D-H, and D-D), where encounters are usually treated as being "commutative" – i.e., H-D has the same result for the Hawk and the Dove as D-H; there is no importance to the ordering of the participants in an encounter. There are circumstances where order does matter, even in symmetric games. For example, where the actor initiating an encounter has an advantage. One can imagine a scenario where in a D-H encounter the Dove and Hawk both survive and go their separate ways unscathed (because the Dove sees the Hawk and flees) while in H-D the Hawk catches the Dove by surprise and takes its bounty.

The second kind of game is asymmetric – the actors do not have access to the same strategy sets, or have unequal knowledge about opponent strategies or the environment. This is often more realistic for evolutionary games; games could play out between two sexes, two ages, two sizes, or territory owners and territory invaders (Maynard Smith 1982). Imagine again the hawk-dove game, but give an extra bonus to one of the two players – whichever player "owns" the territory on which the fight occurs (and such "ownership" is not a variable – the actors have no opportunity to choose whether they are owners or invaders – but instead are assigned one role or the other as a parameter of the game). This is asymmetric, because the players do not have equal access to strategies and knowledge.

Games can also be "zero-sum" or "non-zero-sum." In zero-sum games, the total benefit to all players sums to zero. In other words, a player can only benefit at the expense of other(s). Non-zero-sum games do not have this restriction. Poker zero-sum game, while many games are non-zero-sum, since some outcomes result in net benefit or net loss.

Solution Concepts

You've got to know when to hold 'em, know when to fold 'em, Know when to walk away,

know when to run. The Gambler, by Don Schlitz, sung most notably by Kenny Rogers.

Solution concepts are formally described predictions of how a game should be played to maximize a player's payoff. For example, in most classic formulations of the Prisoner's Dilemma (described in detail in a later section), the rational solution concept is "always defect." For a Hawk-Dove game, a solution concept could be "choose to act like a Dove 40% of the time and like a Hawk 60% of the time," or, equivalently, "40% of the population are pure Hawks and 60% are pure Doves." (This equivalence is explained below in section "[Evolutionary Game Theory](#)"). These percentages depend on relative payoffs. There are many variations of solution concepts in traditional game theory, depending on the motivations of the actors, whether a game is "iterated" (i.e., repeated over time between two actors or in a group of actors), whether a game is symmetric or asymmetric, and more. Any description of a solution to a game is technically a solution concept, whether or not the behavior is deemed normatively good.

Two important categories of solution concept are "Pareto-optimal solutions" and "Nash equilibria." Pareto-optimal solutions feature a distribution of strategies such that no one actor's lot can be improved without hurting the lot of another (Pareto 1896). On the other hand, Nash equilibrium is reached when no single player can improve her own lot by *unilaterally* changing her strategy (Nash 1951). In fact, Nash equilibria are not always Pareto-optimal. Consider the classic prisoner's dilemma game: two prisoners accused of having jointly committed a crime are brought into a divided room; they cannot communicate with each other, but both are told the rules of the game. Each prisoner can either cooperate (with the other prisoner, not with the police!) by staying silent about the crime or "defect" by confessing and trying to gain freedom – figuratively throwing the other prisoner under the bus. If both cooperate, and neither confesses, they each get only 1 year in prison. If both "defect" by confessing, they each get 2 years in prison. And if one defects but not the other, the first goes free

and the second gets 3 years in prison. Nash equilibrium is reached when both players defect; in this case, both players get 2 years of prison, and neither player can improve her own outcome by unilaterally changing her strategy to “cooperate.” If she did, she would receive 3 years in prison while her partner would go free. However, this solution is not Pareto-optimal. The Pareto is reached if both players cooperate and do not confess: here, both players get 1 year, which is collectively better than both players getting 2 years. Obviously, though, this Pareto optimum is not a Nash equilibrium, since if one player defects and confesses, they go free while the other player gets 3 years in prison. In sum, this classic prisoner’s dilemma game illustrates that solutions which are Pareto-optimal are not always examples of Nash equilibria and vice versa. Indeed, if Nash equilibria were always Pareto optimal, game theory would be a good deal less interesting than it is.

Examples and Notation

Let us take a very simple example as illustration. The “Hawk-Dove” game discussed above has also been called the “Snowdrift” game and the game of “Chicken,” names that reflect the diverse research fields which have happened upon mathematically identical games. The games vary slightly by conventional assignment of symmetry versus asymmetry and cost-benefit ratios. Although the names are lighthearted, the “Snowdrift/Hawk-Dove/Chicken” game describes the fundamental underpinnings of mutually assured destruction by nuclear war. Bertrand Russell describes the game of “Chicken” in an extended allegory (Russell 1992) (Fortunately, at least so far, Russell’s fears have proven to be unfounded, possibly displaying some of the limits of game theory, or alternatively of Russell’s employment of it in this context.):

Since the nuclear stalemate became apparent, the Governments of East and West have adopted the policy which Mr. Dulles calls ‘brinkmanship’. This is a policy adapted from a sport which, I am told, is practiced by some youthful degenerates. This sport is called ‘Chicken!’. It is played by choosing a long straight road with a white line down the middle and starting two very fast cars towards each other from opposite ends. Each car is expected to keep the wheels on one side of the white line. As they

approach each other, mutual destruction becomes more and more imminent. If one of them swerves from the white line before the other, the other, as he passes, shouts ‘Chicken!’, and the one who has swerved becomes an object of contempt. . . . The game may be played without misfortune a few times, but sooner or later it will come to be felt that loss of face is more dreadful than nuclear annihilation. The moment will come when neither side can face the derisive cry of ‘Chicken!’ from the other side. When that moment is come, the statesmen of both sides will plunge the world into destruction. (Russell 1992)

Let us imagine a game of Chicken played by two teenagers named Marty and Tory. They drive cars toward each other at high speed, and can choose at the last second to maintain course or to swerve. If both maintain course (strategy “maintain”), they collide and both cars are destroyed. Let us assume that the people inside survive unscathed, because they were wearing seatbelts and had properly functioning airbags, but the financial loss is devastating. If one swerves (strategy “swerve”), she makes it out, car undamaged – but with the label “chicken” and its associated social cost, while her opponent is the brave victor. If both swerve, they both save face. These strategies and payoffs can be represented with a simple payoff matrix:

		Tory	
		Swerve	Maintain
Marty	Swerve	<i>Tie, tie</i>	<i>Coward, Hero</i>
	Maintain	<i>Hero, coward</i>	<i>Crash, crash</i>

In italics within each box, Marty’s choice is represented on the left and Tory’s on the right. In the top left box, both choose to swerve and they tie. In the top right box, Tory maintains course while Marty swerves – so Tory is a hero and Marty is a chicken. We can assign numerical values to these outcomes as follows, assuming catastrophic losses if they collide and minor gains/losses if one swerves:

		Tory	
		Swerve	Maintain
Marty	Swerve	0,0	–1, +1
	Maintain	+1, –1	–10, –10

To simplify matters, let us adjust our notation by writing the payoff matrix only for Marty's expected payoffs:

		Tory	
		Swerve	Maintain
Marty	Swerve	0	-1
	Maintain	+1	-10

Brief inspection of this matrix reveals that the potential loss of swerving (at most -1) is insignificant compared with the risk of staying on course (-10). However, suppose that Tory thinks this through and realizes that Marty will probably arrive at that same conclusion. Might it not be better for Tory to assume that Marty will act reasonably, so Tory can choose to maintain and thus collect the +1 value of being a hero? Formally, this symmetric game has one Nash Equilibrium that is a mixed strategy: swerve with probability P and maintain with probability $(1-P)$. This probability P depends on the payoff matrix; in this case, without writing out the math, $P = 1/10$; each player should swerve 9 out of 10 times and maintain course 1 out of 10 times. On the other hand, if one driver is gifted with the knowledge of what the other driver will do – that is, if we convert this into an asymmetric game – the Nash equilibrium is to “do the opposite of your opponent.”

The “Snowdrift” formulation of the game is somewhere different. Two drivers, Tom and Sam, both get their cars caught in a snowdrift. They each can choose to cooperate by getting out of the car and shoveling in the bitter cold, or defect by relaxing in their cars listening to The Beatles. The benefit b is getting home, while the cost c is shoveling in the cold. If they both cooperate, they can split the work so the cost is $c/2$ while the benefit of getting home remains b .

Here is the payoff matrix, written from Sam's perspective:

		Tom	
		Cooperate	Defect
Sam	Cooperate	$b - c/2$	$b - c$
	Defect	b	0

Clearly, Sam would most like to do no work but nonetheless get home safely – the case whereby she defects and Tom cooperates. Indeed, if $b > c$, the best strategy is to do the opposite of your opponent assuming you have special ability to see their choice (defect if they cooperate, cooperate if they defect). But what if $b < c$ – if the costs of doing the work alone outweigh the benefits of getting home? In that situation, both players are better off defecting.

Indeed, this unorthodox formulation of the snowdrift game wherein solo costs outweigh benefits is mathematically equivalent to the Prisoner's Dilemma. Consider such a case, where the cost of shoveling alone is 6 and the benefit of getting home is 3.

		Tom	
		Cooperate	Defect
Sam	Cooperate	0	-3
	Defect	3	0

Whether Tom defects or cooperates, Sam is better off defecting. If Tom cooperates, Sam could earn 0 or 3 by cooperating or defecting, respectively; if Tom defects, Sam could earn -3 or 0 by cooperating or defecting, respectively. Since $3 > 0$ and $0 > -3$, Sam should always defect. Since Tom will make the same realization, Tom will always defect as well – and we have arrived at equilibrium, sitting inside two cars in a snowdrift listening to The Beatles. (Of course, games where cooperating is the best move for both parties also exist! They just aren't very compelling.)

Conventionally, the name of a game reflects the ranking of payoffs, such that, for example, a “prisoner's dilemma” must have “defect” as the optimal strategy.

These are the building blocks of traditional game theory, which models rational actions and strategies for individuals seeking to maximize their own utility. But the astute reader may notice a flaw: humans are not rational, and utility is not easily quantified. We will discuss this and other drawbacks of game theory in section “Limitations of Game Theory.”

Evolutionary Game Theory

Overview

Evolutionary game theory was founded and developed by John Maynard Smith (Maynard Smith 1982) as well as Karl Sigmund and many others. It was first introduced formally to biologists in 1973 in a *Nature* paper entitled “the Logic of Animal Conflict” (Maynard Smith and Price 1973) and has been used extensively since then. However, prior to the pioneering work of John Maynard Smith, the ideas of game theory were used in evolutionary biology in R. A. Fisher’s work on sex ratio theory (what sex ratio should a female give birth to, given the current sex ratio of the population?), Bill Hamilton’s subsequent work on sex ratio and his introduction of an “unbeatable strategy” (which would give rise to evolutionarily stable strategies), and Lewontin’s work on populations “playing against nature” (Fisher 1958; Hamilton 1967; Sigmund 1993).

Classic game theory models conscious actions and resulting outcomes by individual players; it relies on a premise of rationality and an end goal of utility maximization. How can this method be applied to evolution, to populations of individuals with static traits? Evolutionary game theory plays with Darwinian fitness (instead of rationality) and natural selection (instead of utility maximization). Evolutionary game theory does not require rationality or even conscious thought at all. However, classical game theory does not technically require conscious thought either. The fundamental requirement for game theory is that the success of strategies depends on what others are doing; equivalently, a strategy interacts with the strategy of other actors to determine outcomes. This is perfectly suited to evolutionary systems. Strategies are just traits – phenotypes, in a population – whether the trait is physical, behavioral, or otherwise. Of course, evolutionary game theory does not presume the absence of conscious decision-making; it is equally useful when modeling traits such as cooperation and defection as it is when modeling hair color or genetic conflict.

Evolutionary game theory extends the domain of “games” to include the competition for survival among “agents” – in this case, organisms and

genes. The driving force underlying classical game theory is rational utility maximization, but the driving force in evolutionary game theory is natural selection – in other words, reproductive fitness replaces utility. Finally, “strategies” in evolutionary game theory are biological traits, or phenotypes, that can arise from the interaction between the individual’s genotype (i.e., genetic makeup) and the environment. For example, traits can include brain size, neuronal density, hair color, altruistic decision-making, mate choice preferences, viral deadliness, and aggression in mate competition. Evolutionary game theory models the changes in relative frequency of these traits over time (and over generations) in a population. Its crucial contribution to biological modeling is the ability to interpret situations where an individual’s fitness depends on the proportions of phenotypes in a population and interactions between phenotypes (Nowak 2006a), often exemplified by the value of being a “rare” type in biological systems. For example, if a common virus sweeps through a human population, generally most humans develop an immune response; a new, rare, variant of that virus is far more successful than its precursor. In other words, evolutionary game theory helps us understand frequency-dependent fitness, and phenotypic interaction, both of which are ubiquitous in biological systems (Vincent and Brown 2005).

Like traditional game theory, evolutionary game theory has a solution concept, labeled evolutionarily stable strategies (ESS), which is closely related to the concept of a Nash equilibrium, although those who first described ESS were unaware of Nash equilibria at the time. The defining characteristic of an ESS is that it is “uninvadable” by alternative strategies: when the population is at or near an ESS, that ESS is robust against other strategies. For example, “cooperation” is only a pure evolutionarily stable strategy if the invasion of cheating at low levels would not be favored; indeed, social punishment of cheaters is often seen to be a mechanism by which cooperation remains a stable strategy. In other words, the incremental introduction of alternative strategies cannot successfully invade a population at ESS.

The definition of “pure” versus “mixed” strategies, and their involvement in solution concepts, in evolutionary game theory requires additional explanation. A gene coding for a particular phenotypic trait regardless of environmental involvement is a “pure” strategy for an individual. Imagine a gene in frogs that determines whether a male frog “sings” or “keeps quiet” in its quest to attract a mate. That gene might control with 100% accuracy whether or not a frog sings; in this case, we can describe a solution concept as being a population of “pure strategy” frogs where 30% always sings and 70% always keep quiet. That would be the exact proportion that successfully represents the proportional tradeoff between attracting unwanted attention of predators and attracting the desired attention of potential mates. It is mathematically equivalent to a different scenario: a scenario whereby each individual frog adopts a “mixed strategy” of “sing 30% of the time and keep quiet 70% of the time.” That solution is mathematically identical to a population split between two types of pure strategist frogs.

Biology: Game Theory at Many Levels

Any modern organism is a Russian doll of actually or potentially reproducing units. – Leo Buss (1999)

Selection can act at many levels, and self-interested agents compete for their own purposes in many biological arenas. For this reason, evolutionary game theory has applications in many levels of biological organization, from proteins to populations.

Previously, evolutionary game theory has been conceptualized as two interlocking games: the inner game and the outer game (Vincent and Brown 2005). In the inner game, players interact with one another using “strategies” (phenotypes) and receive payoffs. In the outer game, evolution itself takes place: successful phenotypes (“strategies”) are more frequently passed on, and population phenotypic frequencies alter in response (the inner game and outer game correspond, respectively, to Hutchinson’s ecological theater and evolutionary play (Hutchinson 1965)). In the eyes of evolutionary game theory, a player can be

at one of many levels: a human in a prison; a hyena in a group; a species in a community; an ant colony; cancerous cells within our body; or genes that exist at different frequencies in a population. In classical game theory, players consciously choose strategies from an available array; in evolutionary game theory, players inherit strategies as phenotypes. Further, evolutionary games can have many actors who are strategically identical: same strategies; same payoffs (this can be true of classical game theory as well). In sum, a classic conception of evolutionary game theory maximizes fitness of “agents” by looking at heritable phenotypic “strategies.” In the inner game, mice compete against other mice to gather nutrients and do their best to avoid predators of other species; in the outer game, successful mice pass on their genes which vary in frequency within a population over time.

However, there is a third arena for biological games: within each individual mouse, “strategic genes” (Haig 2012) are playing chess too. As Austin Burt and Robert Trivers write in their landmark book on genetic conflict, “the genes in an organism sometimes ‘disagree’ over what should happen” (Burt and Trivers 2006). For example, whether a particular allele in an individual comes from its mother or father influences its evolutionary “priorities” and subsequent expression, as modulated through a process known as “genomic imprinting” (Haig 2002). (The intriguing phenomenon is too complicated to discuss further here, but refer to ► “Imprinting” in this volume.) Further, genes have many clever strategies to enhance their own transmission, or to change their host’s behavior toward related individuals. Some genes kill off opposing genes and “drive” themselves toward high frequency levels; some genes “overreplicate” to achieve an unfair advantage (Burt and Trivers 2006). Genes interests do not always align with the interests of the organism in which they reside; sometimes they are neutral, and sometimes they even hurt an organism’s fitness. Game theory, in combination with other approaches, can effectively model games between and among genes (Traulsen and Reed 2012). Genetic conflict is a third arena in which competitive or cooperative games play out,

and it is one that clearly influences evolutionary psychology (as we will see below).

Genetic conflict is not the final arena. Just as our own native genes fight with one another, other self-interested players inhabit our body: gut microbes; brain microbes; foreign human cells; viruses; and more are engaged in an ongoing game with our body and each other. These dynamics are perfectly suited to game-theoretical modeling (Nowak 2006a), and these organisms demonstrably impact our psychology and behavior (Kramer and Bressan 2015). The rabbit hole goes deeper still; even proteins folding and enzymes acting in catalytic pathways can be better understood via game theoretical methods (Bohl et al. 2014). But let us not get lost too far in wonderland. Suffice it to note that game theoretical “individuals” in an arena are sometimes arenas themselves.

These interesting, and interlocking, games also complicate a more traditional approach to evolutionary game theory, where “individuals” are coherent beings with unified fitness of all of their parts, instead of arenas where genes and viruses compete for their own selfish interests. We return to this topic below, in “[Frontiers of Game Theory in Evolutionary Psychology](#).”

The Influence of Game Theory on Evolutionary Psychology

Lord, what fools these mortals be! – Robin Goodfellow, *A Midsummer Night's Dream*, William Shakespeare.

Game theory has been helpful in unraveling some of the greatest mysteries in evolutionary psychology. The first and most well-known such contribution involved a series of behavioral experiments in the mid-late twentieth century revealing that our brain has been shaped by evolutionary pressures to think in ways which do not line up with intuitive predictions that our decisions would be guided by rational analysis. These experiments showed that humans are not rational thinkers in a classical sense: we greatly discount the future; are unduly influenced by striking events; exhibit loss aversion, and more. These results opened the door

to questions – which are still the subject of active research – about *what* our brains work to maximize, *how* we process information, and *in what contexts* we depart from pure rationality.

Most subsequent incorporations of game theory into biology concern biological problems which are of interest to evolutionary psychologists, such as sex ratio, parent-offspring conflict (here, we refer to genetic conflict, as described in a previous section), the evolution of language, and the evolution of cooperation (Nowak 2006a). Game theory has helped to model and explain seemingly suboptimal life strategies, such as long-term pairing and cooperation between unrelated humans. It facilitates insights into the maintenance of human psychological variation, and analyses of genetic conflict and subcellular games provide insight into inefficiencies of human behavior and our own social attitudes. Any psychological trait which depends on similar traits in other humans is a good candidate for game theoretical analyses. Below are just a few examples of the wide breadth of research in the field.

Classic Applications: Humans Are Not “Rational”

Game theory's direct influence on evolutionary psychology first arose in the mid-twentieth century, when researchers brought game theory to bear on psychological experiments. This body of work, from the mid-twentieth century to today, is often known as behavioral game theory. A major contribution of behavioral game theory was the observation that human behavior does not line up with what would be expected of a rational, utility-maximizing actor. One of the earliest conducted experiments in behavioral game theory uncovered the Allais Paradox. This describes a phenomenon by which humans given a choice of different lottery conditions make seemingly inconsistent choices with what the expected payoff would be (Allais 1953). The experiment can be written simply as two choices: Test 1 = $[A + X \text{ versus } B + X]$, and Test 2 = $[A + Z \text{ versus } B + Z]$, where each letter represents a payoff and a probability. Since in Test 1, X is consistent between the choices, and in Test 2, Z is consistent between the choices, the rational expectation would be for people to

consistently prefer the first option in both test cases or the second option in both test cases. This, however, is not what experiments demonstrate! Instead, the type of addition contributed by X or Z can make humans, seemingly illogically, choose the first option in Test 1 but the second option in Test 2.

Another classic experiment, which has been repeated with twists for many years, is the “dictator” game, whereby a single player (the “dictator”) can split a cash reward between herself and an assigned receiver (Bolton et al. 1998). She could be given \$10 and decide to split it \$5–\$5, \$7–\$3, \$10–\$0, or anywhere in between. The receiver has no power to reject the split. While it would be “rational” for a dictator to assign all of the money to herself, in reality dictators usually allocate some proportion of money to their receivers. Clearly, humans are not acting solely out of self-interest!

The wealth of behavioral game theoretical studies demonstrates the ways in which humans diverge from purely “rational” behavior. We regret loss more than we appreciate an equivalent gain, we discount the future, we are concerned with building a good reputation, and we change our behavior to benefit others. We are very different than the hypothetical utility-maximizing *Homo economicus*.

Altruism, Cooperation, and Monogamy

Purity is obscurity – Ogden Nash, Reflections on a Wicked World.

Why do humans engage in long-term, formally monogamous pairings? And what can explain our extreme levels of cooperation and altruism? It would seem that such pure actions would be costly to individuals compared with alternatives. However, game theoretical analyses can begin to unravel these mysteries.

We are one of a tiny minority of mammals who exhibit long-term mate pairings. Long-term matings seem to have many fitness costs: for example, committing to one mate means one must forego many other opportunities, and paternity uncertainty means that males risk investing years in someone else’s offspring. In short, it is hard to

explain why individuals with the *opportunity* to mate with many others would not do so. However, when researchers conceptualize long-term relationships as public goods and generate an appropriate game-theoretical model, the payoffs make such an investment worth it (Conroy-Beam et al. 2015). In short, long-term relationships can provide at least three types of payoff: first, mutual investment leads to fewer conflicts of interest than would arise in short-term relationships; second, two-parent investment synergistically combines for a larger resource pool overall; and third, long-term partnership allows for consistent division of labor that leads to specialization and increased efficiency (Conroy-Beam et al. 2015). Further, long-term partnership provides a mechanism to punish “romantic free-riders” who try to drink from the “mutual pool” without investing in it.

Another analysis of monogamy versus polygamy, explained in the book *The Red Queen: Sex and the Evolution of Human Nature* (Ridley 1994) and examined in detail by John Maynard Smith (Maynard Smith and Price 1973), conceives of sex as a game. Imagine a population of polygamous birds, where a new type of “monogamous male” emerges who ends up partnering with one female and raising her offspring, thus increasing the fitness of that baby. Monogamous males are selected over polygamous males. In this manner, monogamy can “invade” a population of polygamy. A more formal mathematical treatment is necessary to demonstrate conditions under which monogamy can resist an invasion by polygamous males.

Robert Trivers, Martin Nowak, Karl Sigmund, and many others have also examined the question of why humans are so cooperative from a game theoretical perspective. (The field is characterized by an ongoing debate between proponents of “inclusive fitness theory,” or kin selection, and its opponents. Interested readers should investigate the primary literature for a more complete account.) Nowak evaluates five mechanisms by which cooperation might evolve, and uses game theory to generate simple rules that must hold true in order for each mechanism to be effective (Nowak 2006b). For example, one of Nowak’s proposed mechanisms for the evolution of cooperation is “direct reciprocity,” whereby you help someone else and

they help you (as if life were a series of repeated Prisoner's Dilemma games). Although it would pay to defect in a one-off Prisoner's Dilemma, things are different in a real-life version of this game, where the dilemma can occur multiple times: over time the strategy of cooperation through direct reciprocity can emerge if the probability of encountering the same individual again exceeds the ratio between costs and benefits of a cooperative act (Nowak 2006b). Similar trade-off equations can be written down for the other four proposed mechanisms: indirect reciprocity, where cooperation buys one a good reputation that moves via gossip among a population, bringing future benefits; kin selection, whereby one's selfish genes are benefited by cooperating with a related individual; network cooperation, where spatial organization plays a role; and group selection, where groups which evolve a cooperative strategy succeed more than anti-cooperative groups (Nowak 2006b).

The evolution of cooperation has been, perhaps, the most exciting and contentious area of game theory (Maynard Smith 1982; Nowak 2006a; Sigmund 1993). It will be examined in greater detail in subsequent sections.

The Persistence of Human Psychological Variation: Rock, Paper, Scissors, Sandpiper

Consider the classic game, "rock-paper-scissors." Rock beats scissors by smashing them; scissors beat paper by cutting it; and paper beats rock by wrapping around it. (Countless children worldwide have shaken their fists at the sky wondering how paper could *possibly* beat rock.) In other words, A beats B, B beats C, and C beats A. Intuitively, we can see that no one strategy is best; the evolutionarily stable equilibrium would be characterized by cycling or by the persistence of stable proportions of different strategies in the population. This may seem to be purely theoretical, but we have now observed many examples of multiple, coexisting strategies in nature. Here is one striking example.

The Ruff, a type of shorebird known as a sandpiper, is so-named for the male's beautiful feather ornamentation reminiscent of Elizabethan collars. However, not all males look the same –

and they do not exist on a continuum, but instead fall into one of three distinct reproductive "morphs:" independent; satellite; and "faeder" (Küpper et al. 2015). Independent males have an elaborate, colored ruff, and display to females in large groups where each male defends a small territory. Satellite males have a white ruff, and mooch off of the independent males' display by lurking around the edges and attracting females when the moment allows. Finally, faeder males are indistinguishable from females; they sneak in and try for quick copulations when females indicate their approval for displaying independent or satellite males. None of these mating strategies is uniformly the best strategy, and the success of one often depends on the persistence of others; indeed, the highest rates of mating overall occur on display grounds which are prominently occupied both by independent and satellite males. Ruffs are Nature's rock-paper-scissors. Intriguingly, these distinct reproductive and behavioral morphs are encoded by a "supergene," a group of genes that are inherited together as a block (Küpper et al. 2015). This unusual genetic mechanism ensures that variation will be maintained in the population, because animals carrying two copies of this inversion cannot survive. In other words, homozygosity is lethal. This is an important genetic feature which drives persistence of multiple phenotypes, and must be taken into account – in addition to the frequency-dependent effects of behavior – in any complete model of sandpipers.

Just as evolutionary game theory helps to explain why the ruff has three consistently present male morphs, it can explain the maintenance of human psychological and cultural variation (Dall et al. 2004; Nettle 2006; Wilson 1998). Stable populations can have multiple strategies, and individual personality traits interact with different tradeoffs of costs and benefits. It is not the case that a single "best" suite of personality traits exists, and formal game theory helps researchers explain why multiple personalities persist in a population.

Here game theory was able to illuminate a truth that was lurking in the shadows, waiting to be noticed.

Frontiers of Game Theory in Evolutionary Psychology

Game theory has already made powerful contributions to evolutionary psychology, as described above. However, there are several frontiers (yet to be explored!) where game theoretical methods will undoubtedly help explain further phenomena. The two most exciting of these are: (i) game theoretical conflicts between “selfish” genes, and their impact on our psyche, and (ii) game theoretical conflicts between non-human inhabitants of our bodies, such as viruses.

The Imprint of Genetic Conflict on our Psyche

I'm afraid that some times / you'll play lonely games too. Games you can't win / 'cause you'll play against you – Dr. Seuss, Oh, The Places You'll Go!

Genes within an organism can have different goals; conflicts within a body between self-interested genes are fertile grounds for game theoretical examination (Burt and Trivers 2006; Haig 2002). Further, this is particularly relevant to evolutionary psychology because genetic conflict is specifically and tightly connected to human behavior and psychology (Haig 2011). “Imprinted” genes, which are a representative hallmark of genetic conflict between maternal and paternal interests, are “highly prevalent” in the brain, with functions ranging from cognition and sociality to synaptic plasticity (Perez et al. 2016). Relationships between mother and child; our attitudes toward close and distant relatives; our respect affinity for and behavior towards maternal versus paternal kin; the timing and nature of sexual maturation; and other traits are all to be likely impacted by the genetic conflict present between genes of maternal and paternal origin (Haig 2011). Indeed, experimental, anthropological, and epidemiological evidence all support the connection between genetic conflict and evolutionary psychology (Haig 2011). For example, certain “imprinting” diseases, which reveal the hidden battle within our genomes, predictably affect behavior and

psychology (see ► “Imprinting”). Beneath these psychological and behavioral patterns lie game theoretical conflicts at the level of the genome.

We can take our inference one step further back: when genes within an organism are fighting, rather than purely cooperating, they will likely lead to suboptimal functioning. War expends resources! Could competition games between genes explain “inefficiencies of mental function” and the “high frequency of pathology in human social interactions” (Haig 2011)? Imprinted genes are particularly enriched in the brain (Perez et al. 2016), and human social interaction is a major determinant of individuals’ fitness. Therefore, mathematical analysis of the relative “strategies” of genes and alleles in opposition could provide fruitful inquiry into human psychological inefficiency and pathology.

Humans: Camper Vans for Competing Microorganisms

Curiouser and curiouser! – Lewis Carroll, Alice in Wonderland.

Humans are not coherent individuals that single-mindedly seek to improve fitness. Instead, our body plays host to a vast array of gut microbes, brain microbes, viruses, and invading human cells that compete to exert influence within the body. Further, these agents – and their game theoretical competition – impact our everyday psychology and behavior, both by accident and by design (Kramer and Bressan 2015). Anxiety, depression, schizophrenia, and more all have demonstrable connections to the small, selfish agents hitching a ride in our bodies.

Influencing the mind is like influencing the president of the USA – the mind can powerfully influence fitness, since it provides executive control (conscious and unconscious) over so many other bodily functions. For these reasons, small, selfish agents have strong motivation to hijack our brains.

A most unsettling example comes from *Toxoplasma gondii*, a unicellular protozoan parasite which passes between the brains of mice and rats and the muscles of cats (and, as it turns out, the

brains of humans). *Toxoplasma*'s life cycle requires that it develops as an egg inside cat intestine; therefore, the mature organism has an incentive to manipulate rats and mice to be eaten by cats. Indeed, in rats, *Toxoplasma* demonstrably makes the rat *less afraid of cats*, slower to react to stimuli, and, in some cases, sexually attracted to cat urine (Webster et al. 2013). Though humans are not intended hosts of *Toxoplasma* (the parasite cannot complete its life cycle after entering a human host because human brains are rarely eaten by cats), *Toxoplasma* can take up residence in a human brain. Recent evidence shows that *Toxoplasma* infection is tightly connected to a wide variety of mental deficiencies, from slow reaction times to schizophrenia and depression (Kramer and Bressan 2015; Webster et al. 2013). Some evidence strongly indicates that it is causal of, not merely correlated with, mental disease (Kramer and Bressan 2015).

The evolutionary dynamics of viruses and other small, selfish agents have recently been unpacked effectively with evolutionary game theoretical methods (Nowak 2006a). Common wisdom holds that a small, selfish invader cannot be too deadly, or it will exhaust its supply of hosts and not be able to be successfully transmitted. This makes sense. But there are many virulent diseases that appear to violate this principle! What dynamics lead to the evolution of virulence? What is the "health" outcome of many small selfish agents competing within a single host? In what context can virulence paradoxically be maintained over time (as in the case of human malaria)? High virulence can be a successful strategy if the population of hosts is large or sub-divided enough that the parasite is not at risk of depleting it. Mathematical analysis indicates that evolution maintains stable proportions of viruses with different levels of virulence over time, and that linkage between ability to infect a host and virulence maintains virulence beyond what would seem to be ideal levels for the parasite (Nowak 2006a). But virulence well in excess of the transmission-viability equilibrium can be selected for as well when different parasites compete within the same "superinfected" host. When a single host is invaded by many

microparasites, they compete; this competition leads to (i) coexistence of parasites with a range of virulences, (ii) higher average virulence to the host than single infection would generate, and (iii) complicated dynamics with the potential for surges in virulence (Nowak 2006a).

The connection between mental health and our microbiome is a trending topic in medicine (Foster and Neufeld 2013). Fecal transplants and oral ingestion of gut bacteria to cure gastrointestinal ills are all the rage, and gut microflora clearly affect mental state (Foster and Neufeld 2013). But in order to properly treat mental illness in connection with our microbiome, we must properly understand the evolutionary dynamics. Competing individual agents interact in complex webs within our body, with the potential for catastrophic spikes (Nowak 2006a). Some of these agents share our interests in bodily health, and some do not. Lest we interfere in the wrong manner, we must employ game theory to understand the connections between and among microorganisms in our body – and their demonstrated effect on our psychology.

V. Limitations of Game Theory

Traditional Game Theory: Poor Assumptions about Humanity?

Man is many things, but he is not rational – Oscar Wilde, *The Picture of Dorian Gray*.

Many real-world phenomena interfere with our predictions about human behavior and reasonable solution concepts for a given game. Humans are not always rational in an economic sense; myriad factors can interact to influence the outcome of a game (including, for example, intangibles such as social pressure). It is possible that humans are rational, but that we cannot conceive of all perceived costs and benefits, nor quantify them. Behavior which may seem irrational, because it comes at a cost to the individual while helping a stranger, might actually serve a "hard to quantify" purpose, such as building reputation or providing a "warm glow" of good feeling to the helper. Thus, classical game theory cannot always

estimate the sum of people's true utility. It has also faced some methodological criticism: for example, laboratory experiments cannot be a perfect proxy for reality (Gintis 2009). People are aware that they are in an experiment and behave in unusual ways.

Further, a "trembling hand" or "fuzzy mind" is used as shorthand for the prevalence of mistakes, behavioral or phenotypic, that might lead someone to mistakenly play the "wrong" strategy or misremember what their opponent has done so far. In more detailed examinations of game theory, theorists and experimentalists test proposed solution conceptions against "trembling hands," or occasional errors. Since the real world is filled with errors, a solution strategy must be robust against a "trembling hand" (rather than irrevocably altered by one). It is said that "close" only matters in horseshoes and hand grenades; we now know that "close" should also matter for successful game theory solution concepts!

Complications of Heritability and Individuality: A Crisis for Evolutionary Game Theory?

In physics, every crisis is an opportunity – Richard T. McCoy, *Physics of Time* (The Princeton Time Project).

The aforementioned complications about genetic conflict, and the multiple hierarchies of players within a single body, raise two major criticisms of evolutionary game theory at high levels. Generally, in evolutionary game theory, we deal with "individuals" who pursue high "fitness" for themselves. Both "individual" and "fitness" encode hidden assumptions.

The maximizing principle of "fitness" assumes that selection operates on observable, heritable phenotypes in a direct and effective manner. For example, the trait of "cooperation" in a population is often modeled as a simple, consistent, and perfectly heritable trait, although in fact it can be (i) influenced by the joint action of many unlinked genes, (ii) variable in different environments and across contexts, and (iii) underpinned by complex gene-on-gene battles. In fact, a fascinating result

from a type of colonial marine invertebrate, ascidians, demonstrates that apparent superficial cooperation – the fusing of two colonies – is in fact a brutal example of parasitism, where one colony becomes disproportionately represented in the germline (Buss 1999). Although the colonies seem to be fusing and sharing resources, one wins the Darwinian game and one loses. If we were to model this as a game without full knowledge, it would seem that both players benefit from the arrangement – and this is clearly not the case. This is an illustration of a now well-known theory: that the history of life is a history of "conflicts between units of selection" (Buss 1999). Characteristic features of life's organization – such as mitochondria within a cell, microbes within a body, ants within a colony, and so forth – evolve to suppress parasitism at lower levels. Is all apparent cooperation underpinned by conflict? Games are not always as they seem.

Second, "individuals" are really complicated battlegrounds for bacteria, viruses, warring genes, "chimeric" cells from distinct genetic individuals, and more. A marmoset, for example, is born as one of a nonidentical twin pair that freely swaps cells in the womb (Haig 1999). That is, an "individual" marmoset is actually a composite of two genetic individuals – a mosaic of cells with two distinct genomes, one being "itself" and the other its twin. In an evolutionary game, is an individual marmoset pursuing fitness for itself, its body? Or for a genetic individual? *Which* genetic individual? These are not simple questions. Further, humans often conflate evolutionary fitness with lifetime happiness; however, often the brain works in ways that seem counter to our day-to-day happiness but have understandable evolutionary underpinnings.

Does our richer understanding of heritability and the dynamics between levels of selection render high-level game theory useless?

In a word: no; high-level game theory is still fruitful. (Otherwise, this could have been a much shorter chapter.) Unless we have reason to suspect particularly unusual mechanisms of inheritance, the fact of heritability, rather than the details thereof, is often sufficient for game theoretical purposes (Vincent and Brown 2005). Darwin did

not even know what the unit of heritability might be – he merely postulated that like begets like, organisms struggle to exist, and heritable traits influence the struggle. The mechanisms of inheritance are useful for many purposes, but they are not *particularly* essential to studies of broad evolutionary dynamics.

Nonetheless, it is worth being aware of complications of heritability, particularly those arising from genetic conflict. Indeed, these complications are more “opportunity” than “crisis:” they provide fertile ground to employ game theoretical methods at many levels, from proteins to populations.

In *A Brief History of Time*, Stephen Hawking relays the following anecdote: “A well-known scientist (some say it was Bertrand Russell) once gave a public lecture on astronomy. He described how the earth orbits around the sun and how the sun, in turn, orbits around the center of a vast collection of stars called our galaxy. At the end of the lecture, a little old lady at the back of the room got up and said: “What you have told us is rubbish. The world is really a flat plate supported on the back of a giant tortoise.” The scientist gave a superior smile before replying, “What is the tortoise standing on?” “You’re very clever, young man, very clever,” said the old lady. “But it’s turtles all the way down!””. Countries compete on Earth, political parties compete within countries, humans compete within political parties, and viruses compete within humans: it’s game theory all the way down!

Conclusion

Game theory, and its cousin Evolutionary Game Theory, have set the stage for evolutionary psychology on multiple levels. Game theory provided mathematical tools for interpreting systems where individual success depends on the strategies of others – i.e., all human interactions. It also revealed truths about the human brain- that we are not rational according to economic definitions, and that interesting features of the mind lurk in areas where we deviate from predicted rationality. Evolutionarily game theory placed these methods and topics into a biological context, which allows

us to interpret complicated phenomena such as the evolution of altruism and monogamy. Games are played in many arenas ranging from the internal wiring of our brain to complicated displays aimed at attracting a life partner to international politics. Perhaps one day games will be played among the stars. In all of these domains, the game theory will illuminate many secrets waiting to be discovered.

Definition

The sizes of reproductive cells in sexual reproduction.

Introduction

Female gametes are larger than male gametes. This is not an empirical observation, but a definition: in a system with two markedly different gamete sizes, we define females to be the sex that produces the larger gametes and vice-versa for males (Parker et al. 1972), and the same definition applies to the female and male functions in hermaphrodites. Although asymmetry in gamete size rather than number is usually used as the defining characteristic, size dimorphism has the almost inevitable consequence that females produce fewer gametes than males due to a simple physical trade-off – larger things can be produced in smaller numbers, given a limited amount of resources. Therefore, in practice females differ from males in terms of both gamete size and numbers. This definition of the two sexes is a very simple one, yet it leads to some intricate, surprisingly difficult, and even controversial questions concerning both the origin and consequences of gamete size dimorphism. Given that these questions relate directly to the origin of the two sexes, this is a topic that captures the attention of scientists and the public alike.

Isogamy and Anisogamy

Anisogamy refers to gametic systems where gametes are dimorphic in size: one gamete type is larger (e.g. ova) than the other (e.g. spermatozoa), and gametic fusion occurs only between the larger and the smaller gametes, while *isogamy* implies that all gametes are of similar size (Lehtonen and Parker 2014). Therefore, only anisogamous species can be said to have male and female gametes, and in this sense the origin of anisogamy is synonymous with the origin of the two sexes. Both isogamous and anisogamous species exist today, with a fascinating range of organisms from isogamy all the way to highly dimorphic anisogamy, and our ancestors were almost certainly isogamous (Lessells et al. 2009). Given that our ancestors had a gamete size ratio of 1:1, why is it that a ratio of 10^6 :1 is now not uncommon in nature?

Evolution of Gamete Size

Theoretical work over several decades has focused on understanding the selective pressures that result in disruptive selection on gamete size. An early model (Kalmus 1932) showed that if a fixed amount of total provisioning from gametes is required for zygote development, then under some conditions the highest population-wide rate of successful fertilizations is achieved if gametes are highly dimorphic. However, this argument relied on outdated group selection thinking, and the first argument fully grounded in individual level selection was based on competition between gametes for fertilizations (Parker et al. 1972): while ‘proto-females’ (parents producing large gametes) can produce zygotes with high survival, ‘proto-males’ (producing many small gametes) gain a large fraction of fertilizations with these large gametes, benefitting from their zygote provisioning in an almost parasitic way. There are therefore incentives to increase gamete size on one hand (higher offspring survival), and increase gamete numbers on the other (larger proportion of total fertilizations via primordial sperm competition). Here selection is not assumed to benefit the group or species, but is driven largely by individual level benefits in competition for fertilizations. These two approaches have often been called ‘gamete limitation’ and ‘gamete competition’ theories for anisogamy evolution, and the gamete competition theory (Parker et al. 1972) has been widely accepted as a likely evolutionary explanation for anisogamy. However, it has since been shown that these theories are not mutually exclusive, and can in fact act in the same direction and reinforce each other (for a review of gamete limitation and gamete competition theories, see Lehtonen and Parker 2014). There is also an alternative suite of theories that are based on so-called intracellular conflicts: evolutionary conflicts of interest between cytoplasmic and nuclear genes carried by gametes. These theories originate with Cosmides and Tooby (1981), and are reviewed in Lessells et al. (2009). However, current evidence suggests that intracellular conflicts are unlikely to be the main driver of the

evolution of anisogamy (Lessells et al. 2009). Although models of anisogamy evolution generally predict a unidirectional divergence in gamete sizes, it is also possible for sexual selection to drive a secondary increase in sperm size, such as in some *Drosophila* species (Lüpold et al. 2016). Although sperm size can secondarily approach egg size in these cases, this is not an evolutionary reversal per se, as the two gamete types remain clearly morphologically distinct.

Evolutionary Consequences of Gamete Size Dimorphism

Given that we have an understanding of evolutionary pressures that select for gamete dimorphism, the next obvious question is whether an asymmetry at the gamete level selects for further asymmetries at the organism level. Is there a logical, causal link from gamete size to morphological or behavioural traits that are observed in males and females in nature? Should we expect one sex to be more competitive over fertilization opportunities than the other? Should we expect one sex to more commonly care for offspring than the other? These are not new questions. In 1871 Charles Darwin already wrote *‘We are naturally led to enquire why the male, in so many and such distinct classes, has become more eager than the female, so that he searches for her, and plays the more active part in courtship. It would be no advantage and some loss of power if each sex searched for the other; but why should the male almost always be the seeker?’* (Darwin 1871). Bateman (1948) later provided a famous empirical justification for why males should be more strongly selected to compete for matings: his experiments showed that male fertility in *Drosophila* is more dependent on frequency of insemination than female fertility. Bateman’s result is still very influential, but there is nevertheless lingering controversy over whether differences in gamete size really drive sex-specific selection patterns. A recent theoretical argument demonstrates how such a link can come about using simple principles of resource trade-offs and fertilization probability (Lehtonen et al.

2016): As a thought experiment, imagine an ancestral organism where males and females are initially absolutely identical apart from differences in gamete size. Next, decompose fitness w into two multiplicative components, gamete number n and probability of fertilization of each gamete p , so that $w = np$. Assume there is a trade-off between resource investment into gamete number n and into a sexually competitive trait that increases p . This trait could be anything that affects fertilization probability, either at the organism level or gamete level, such as male-male combat or faster swimming sperm. Now, because male gametes outnumber female gametes (often by a very large margin), it is possible that $p = 1$ for females, but not for males, and in most cases, p is inevitably much lower than 1 for males. Therefore, as long as fertilization probability of female gametes is high (p close to its maximum value 1), it is clear that males are more strongly selected to divert resources to sexually competitive traits that increase p . The asymmetry in gamete numbers therefore creates a simple asymmetry in gamete-level fertilization probabilities, which creates asymmetrical, male-biased selection to increase this fertilization probability. This asymmetry can be shown to persist even when female fertilization is incomplete ($p < 1$ for females as well as males), although the asymmetry does diminish with increasing sperm limitation (Lehtonen et al. 2016). Recent theory (Fromhage and Jennions 2016) also confirms that individuals benefit less from caring for their offspring when they face stronger sexual selection and/or lower certainty of parentage, both of which are often expected to be associated with smaller and more numerous gametes. The latter is clearest under internal fertilization, where a female who receives gametes from males can be sure that she is the mother of the offspring that she carries, even if she and her male partners have had multiple mating partners. A male, on the other hand, can only be certain of paternity if he is certain that his mating partner has not mated with anyone else. Therefore males run a risk of caring for offspring that have been fathered by others, creating an asymmetry in the benefits of parental care.

Conclusion

Gamete size is the defining feature of the male and female sexes. Our ancestors were isogamous, meaning that they produced gametes of just one size, and hence had no separation into male and female gametes or male and female sexes. The evolutionary origin of the two sexes is therefore intimately tied to the evolutionary divergence of gamete sizes, which in turn is likely linked to the trade-off between provisioning zygotes with large gametes, and producing a larger number of smaller gametes. Although some controversy has surrounded the connection between gamete size and the subsequent evolution of sex-specific behavioural traits that we observe in nature, evolutionary theory now also demonstrates clear logical connections between gamete size, sexually competitive traits, and parental care.

Definition

Membership in a group wherein its members have a high degree of interaction, similarity, as well as mutual interests and goals that are often achieved via criminal means.

Introduction

Membership in gangs is associated with increased involvement in violent crime (Bjerregaard and Smith 1993; Esbensen and Huizinga 1993). This presents obvious risks, including the potential to be physically harmed during violent altercations and to be prosecuted for crimes committed. Given these risks, there are likely benefits of gang affiliation that offset these costs. Here we describe the structure of gangs and what benefits might accrue to members of gangs.

Entitativity of Groups

Groups vary in the extent to which they are perceived as a coherent entity; this entitativity or “groupiness” (Dasgupta et al. 1999) is determined by a number of factors. In particular, entitative groups exhibit a high degree of interaction, rate membership in the group as important, have shared goals, mutually dependent outcomes, a high degree of similarity across members, low permeability, smaller size, and a long duration (Lickel et al. 2000). Gangs exhibit many of these characteristics. Indeed, when participants were asked to rate the entitativity of forty different groups, gangs were rated in the top five of the most entitative groups (Lickel et al. 2000).

Entitative Characteristics of Gangs

Over many years researchers have developed a variety of definitions that attempt to paint a picture of the essence of gangs. Thrasher (1963) defined gangs on the basis of six characteristics: cooperation as a result of external hostility, direct relations, organization, spontaneous origin, common tradition, and partiality for a particular geographic area. Many of the characteristics described by Thrasher (1963), as well as others discussed below, map on to attributes of entitativity. First, there is a high degree of interaction, particularly considering their preference to occupy a particular territory or geographic area. Indeed, proximity to a gang, and therefore an increased likelihood of

interaction with gang members, is a major risk factor for joining a gang (Decker and Curry 2000).

Individuals’ motivation to join gangs reflects their shared goals and high degree of interaction. Decker and Curry (2000) examined factors that influenced individuals to join gangs. These factors include status obtained through interactions within and outside of one’s specific gang, respect among peers, family affiliations within gangs, protection from external dangers, and access to mating opportunities. Miller’s (1980) definition of gangs also exemplifies the shared goals and outcomes among gang members: “A youth gang is a self-formed association of peers, bound together by mutual interest, with identifiable leadership, well-developed lines of authority, and other organizational features, who act in concert to achieve a specific purpose or purposes” (1980, p. 121). Based on Miller’s definitions the basic structure of gangs may not be all that different from other groups; however, the shared goals of members (e.g., acquisition of power and resources) tend to be manifested in the form of criminal activity.

Although gang membership is not isolated to any particular demographic, research suggests that males, Hispanics, and Blacks are more likely to be involved in gangs than females or other races (Hill et al. 1999). Moreover, there appears to be a high degree of similarity within gangs on the basis of socioeconomic status, ethnicity, race, and religion. For example, gangs present in other nations have a strong degree of religious homogeneity (Covey 2003). Homogeneity of gang membership on the basis of race, sex, and ethnicity, within gangs, has been documented in the United States, as well as Canada (reviewed in Martin 2005) and the United Kingdom (Covey 2003). Gangs also express their similarity through their shared identification under a particular group name (Klein 1971).

Average size of gangs, as well as the duration and permeability of membership is difficult to determine because there are varying degrees of gang involvement. Membership may consist of peripheral followers that only socialize with the gang, solidified but short-term membership, and extremely loyal and committed, long-term members. Thus, on the whole gangs may be large and

permeable (some of the largest gangs in the United States have 8,000–10,000 members; Swecker 2005), but the core group of veteran members is likely to be small, difficult to penetrate as a new member, and of long duration. Moreover, this highly structured, hierarchical nature of gang membership likely also contributes to the perception of entitativity.

Overall, this information is helpful in describing gangs, yet does not provide an explanation for why gangs exist, for that it is useful to turn to an evolutionary perspective.

An Evolutionary Perspective on Groups

Throughout human evolutionary history living among other people afforded humans many advantages, including the ability to: acquire and protect resources and territory necessary for survival, practice specialized labor, select long-term mates, and be protected from predators and conspecific threats. Given the many advantages to group living afforded to our evolutionary ancestors, it is not surprising that modern humans express a strong motivation to “belong” to groups (Baumeister and Leary 1995). Even more telling is the psychological distress experienced by individuals who are excluded from a group, even when that group is novel and relatively unimportant for one’s social identity (Williams 2009). These features of human psychology are indicative of psychological mechanisms that function to increase reproductive fitness by promoting the formation and maintenance of group bonds.

Among humans’ hunter-gatherer ancestors, groups existed at multiple levels, ranging from small kinship-based bands (25–100 individuals) to tribes of multiple kin groups, and large societies that encompassed many individuals sharing the same cultural system or language in a particular region (a few hundred or thousand individuals) (Wrangham and Glowacki 2012). Reviewing the anthropological evidence, Gat (2015) has suggested that conflict occurred between groups at all of these levels. This shifting of coalitional alliances suggests that humans are likely equipped

with flexible cognitive machinery for adopting novel coalitional memberships, and quickly detecting the relevant coalitions in a given environment.

Indeed, research supports both claims. Research on “minimal groups” has demonstrated that individuals who are assigned to a novel group on the basis of largely arbitrary criteria, such as a coin flip, painting preferences, or the tendency to over- or underestimate dots, display a preference for their minimal ingroup members over the outgroup (e.g., Tajfel and Turner 1986). Moreover, research by Kurzban et al. (2001) has demonstrated that individuals encode novel coalitional memberships on the basis of cues of verbal allegiance and visual similarity (i.e., shared style of dress), even when they are not told to do so. Overall, these findings suggest that humans may be quite tribal, able to quickly adopt group identities that may serve their interests, and to quickly identify the coalitional alliances of others in the local environment.

The Function of Gangs

Gangs appear to serve a similar function as coalitional groups did for our evolutionary ancestors. Members are often connected by kinship, they work together to protect their territory, and to acquire and defend their group’s resources. Moreover, they engage in aggressive behavior against other groups to increase their access to resources. That gangs tend to achieve these goals through illegal activity is likely a result of the low socioeconomic status of the members, and the lack of opportunities to ascend a status hierarchy using legal means. Strong loyalty to one’s gang likely facilitates greater ability to protect one’s resources in a highly volatile environment where intergang conflict is common. Gang signs, symbols, and names serve as indicators of membership and further perpetuate the strong divisions that exist between rival gangs.

The tendency for gangs to be largely male dominated (Jaggers et al. 2013) is also consistent with evolutionary theorizing. The theories of

parental investment and sexual selection are necessary for understanding why this is the case. Parental investment theory (Trivers 1972) argues that differences in the reproductive physiology of males and females incentivize different reproductive strategies. In particular, males and females differ in the minimum level of investment that is required of each sex to produce viable offspring (Trivers 1972). The obligatory investment for males ends after fertilization, but females bear the costs of gestation, birthing, and lactation. Men and women also differ in the length of their reproductive lifespan, with men capable of producing offspring for far longer than women. As a result, over a lifetime men can produce many more offspring than women.

As the lower investing sex with a longer reproductive lifespan, males benefit to a greater extent than females from engaging in competition with other males for access to mating opportunities. Through the process of intrasexual selection, this male-male competition exerts selection pressure for traits that increase success in competition. These traits include physical features, such as greater muscle mass and upper body strength (reviewed in Sell et al. 2012), as well as psychological characteristics, such as a greater inclination to use aggression and a stronger desire to achieve high status, compared to women (Archer 2009).

Competition among males for access to reproductive resources may be direct, such as physical contests for sexual access to mates, and indirect in the form of competition for resources that can be leveraged to increase one's appeal to females, including status. Importantly, this competition for increased resources can occur within a group, but also between groups, where one group of men attack another group to take their resources (McDonald et al. 2012). Overall, this perspective suggests that the greater tendency of males to engage in violence and aggression is due to the reproductive benefits awarded to males who succeed in male-male competition.

In contrast, there are comparatively low pay-offs available to women who invest heavily in competition with other women. Females' large investment in offspring makes their presence

particularly important in the survival of offspring. Indeed, the death of the mother is more likely to lead to the death of the child than the death of the father, an effect which is particularly dramatic in the first year of life (Campbell 2005). Thus, the costs of aggression for women are extremely high, and likely created selection pressure to inhibit aggressive behavior.

Given these sex differences in reproductive strategies and intrasexual competition, it is not surprising that gangs are largely comprised of men. There are greater reproductive incentives for them to protect and defend a territory that provides them with resources, particularly given that doing so often requires violent competition. Evidence for this comes from research demonstrating that male gang members, particularly those in high-status positions, have higher mating success than non-gang members (Palmer and Tilley 1995). That this behavior is relatively rare in females is consistent with the fact that engaging in violent competition for access to reproductive resources is less able to be converted to reproductive resources in women, and is potentially very costly if it leaves a woman unable to care for her offspring (Campbell 2005).

Conclusion

Gangs represent a highly cohesive group, displaying many features of entitativity. Membership in gangs appears to serve many of the same benefits as were afforded to our evolutionary ancestors living in groups, namely acquisition and protection of resources and territory, increased mating opportunities, and protection from conspecific threats. Thus, although entrance into a gang comes with great costs, the benefits of membership appear to outweigh its risks, particularly for men.

Shortcomings in and criticisms of the theory *Origin of Species* related to Darwin's/Wallace's theory of natural selection and how those gaps were filled.

Introduction

This entry focuses on gaps in the initial theory of Charles Darwin in his 1859 book *On the Origin of Species by Means of Natural Selection or the Preservation of Favoured Races in the Struggle for Life* and its six subsequent revisions. This work can be summarized as two major arguments (Bowler 1989): First, it argued that species evolved via a process of “descent with modification.” Second, it argued that this process was driven by natural selection, an evolutionary mechanism co-discovered with Alfred Russel Wallace that required a struggle for existence, variation with fitness consequences, and inheritance of that variation. This work remains standing as a centerpiece of current evolutionary thought. Despite this, acceptance of Darwin's work was never smooth sailing, as it faced a mix of criticism and praise from scientific and societal communities. Some bona fide gaps in the original theory were exposed by these critiques. Darwin was clearly moved by some of the criticism, as is

evidenced in the book's revisions and in his correspondence with intellectual contemporaries. Other gaps existed but it is unclear whether Darwin recognized them.

By necessity, the coverage of gaps in this entry is somewhat selective but includes (a) arguably the most important gap in the lack of a proper understanding of genetics; (b) gaps of immediate relevance to researchers interested in the evolution of human behavior, including evolutionary psychology, in the theory's inability to explain seemingly maladaptive traits; and (c) gaps in the macroevolutionary claims in Darwin's early work which are of relevance for understanding the early theory's relevance for human evolution.

Fleeming Jenkin's Critique

In 1867, Scottish engineering professor, Fleeming Jenkin (Fig. 1), published a review of *Origin of*

Gaps in Darwin's Initial Theory, Fig. 1 Fleeming Jenkin, a Scottish engineer, published a three-part critique of Darwin's initial theory. Darwin conceded to Jenkin with regard to the inheritance of variation but was unmoved by his criticism that the earth was insufficiently old. (Henry Charles Fleeming Jenkin. Etching by W. Holl, 1884. Credit: Wellcome Collection. CC BY)

Species wherein he advanced a three-part critique of Darwin's ideas (Gayon 1998). The critique exposed two gaps in the initial theory and another that rested on reasonable-for-the-time theory that was later disproved.

The most famous of his criticisms centered on the inadequacy of blending inheritance, the mechanism favored by Darwin and his contemporaries, for sustaining natural selection (Charlesworth and Charlesworth 2009). Even when a trait confers a selective advantage, offspring fail to inherit it due to the “swamping effect” of blending. Rather, they will inherit a phenotype intermediate between their mother’s and father’s. Despite Jenkin’s belief that this was problematic for the inheritance of small changes, but not large ones (referred to as “sports”), Darwin’s theory rested on the accumulation of small changes. Darwin conceded to Jenkin in subsequent editions of *Origin of Species* and in a letter to Wallace. Jenkin’s criticism lost its bite with the eventual acceptance of Mendel’s principles, which were published 2 years prior to the publication of Jenkin’s review, but did not receive wide circulation until the turn of the twentieth century (Bowler 1989; Charlesworth and Charlesworth 2009; Gayon 1998). This paved the way for the “Modern Synthesis” – a new understanding of evolutionary processes and their consequences based on a tying together of Mendel’s and Darwin’s (and Wallace’s) ideas.

Jenkin offered two additional points of criticism (Gayon 1998). The second was that variability within a species was bounded and that natural

selection, thus, was insufficient to drive speciation. This is discussed in further detail below. The third criticism was that the earth was insufficiently old to have supported the evolution of its diverse life forms. This was a direct refutation of geologist Charles Lyell’s findings, on which Darwin’s theory was propped, that the earth was sufficiently old to have allowed “virtually unlimited amounts of time” (p.206) for evolution to have occurred (Bowler 1989). Jenkin’s point here was based on a critique of Lyell’s work by Lord Kelvin. Darwin was unconvinced by this part of Jenkin’s criticism, which was for the best as Kelvin was proved wrong by advances in early twentieth century physics (Bowler 1989).

Explaining Seemingly Nonadaptive Traits

Darwin (1859) viewed his theory as providing a mechanism that would favor individually beneficial traits, never those that were “injurious to itself as natural selection acts solely by and for the good of each” (p.201). Explaining the existence, and thus evolution, of seemingly nonadaptive traits – such as aesthetic displays and altruism – was a gap in Darwin’s initial theory (Fig. 2).

Darwin felt that his initial theory could not explain the evolution of exaggerated or purely ornamental features on the basis that they appeared nonadaptive (Bowler 1989; Cronin 1991; Jones and Ratterman 2009). In a letter written in 1860 to his friend, American botanist Asa Gray, he opined that “the sight of a feather in a peacock’s tail, whenever I gaze at it, makes me

Gaps in Darwin's Initial Theory, Fig. 2 Nonadaptive traits posed a problem for Darwin's initial theory: (a) extravagant displays, such as the peacock's train, were viewed as nonadaptive in the context of regular natural selection; as shown on the left, they might attract the attention of or slow the escape from predators. Darwin later elaborated the theory of sexual selection which can

favor these traits when they provide a mating benefit (as shown on the right). (b) Altruism, defined as behavior that benefits others at a cost to individual fitness, was a problem for Darwin's original theory that took a century to solve. There is a debate over whether Darwin himself recognized it as a problem

sick!” Darwin presaged his eventual solution to the problem in *Origin of Species*, but it was in his second major work, *The Descent of Man, and Selection in Relation to Sex* (Darwin 1871), that he detailed the theory of sexual selection. In essence, he argued that it worked via two mechanisms: female choice (intersexual selection) and direct male-male competition (intrasexual selection). Darwin and Wallace disagreed about both mechanisms. Wallace argued that female choice could not have driven evolution and that traits that may have arisen via male-male competition, such as an elk’s antlers, would evolve via regular natural selection for utilitarian purposes. Although Darwin was correct in essence, and there were some advances in the interim, sexual selection did not become part of the canon of evolutionary theory until the second half of the twentieth century (Cronin 1991).

Another problem with Darwin’s initial theory was its inability to explain the evolution of altruism – those behaviors that provide a fitness benefit to others while incurring a cost to the actor (Cronin 1991; Dugatkin 2007; Ratnieks et al. 2011). Altruism includes, of course, traits such as alarm calling and providing care to young by parents and others. Darwin singled out the evolution of sterile workers in honeybees, something that today is viewed through the lens of altruism, as posing a “special problem” for his theory (Darwin 1859, p.236). While some see this as evidence that he puzzled over the evolution of altruism (e.g., Dugatkin 2007), others argue that he never recognized the problem as such (Cronin 1991; Ratnieks et al. 2011). Regardless, it was a gap in the initial theory, and a satisfactory solution, despite being presaged by Darwin and others following him (Dugatkin 2007), was only offered with the formulation of inclusive fitness theory in the later half of the twentieth century. The delay in resolution, though certainly attributable to a multitude of factors, may have been caused to some degree by the debate over individual versus group selection (Domondon 2013; Ratnieks et al. 2011).

The Origin of Species and Transitional Forms

The lack of evidence for the second of Darwin’s main claims, and the element of the theory from which derived the name of his most famous

work – that natural selection would lead to the origin of new species – was an important problem for his theory. Huxley, for instance, who was otherwise one of Darwin’s most vociferous allies (his “bulldog”), argued that the most conclusive evidence for selection would come when it can be shown to “produce a new species” (as quoted in Bowler 1989, p. 195). Darwin’s erroneous ideas about what constituted a species have been pointed out as another weakness (Mallett 2008). Nonetheless, Darwin’s ideas about the mechanisms that would drive speciation – geographic isolation – mirror modern ideas on allopatric speciation but downplay the ability of speciation to occur without it, which is today referred to as sympatric speciation.

Another related gap in the initial theory was the lack of “transitional forms” (Bowler 1989). Darwin claimed in *Origin of Species* that fossils supported his theory but understood that there were weaknesses in the evidence. For instance, he argued at length that the gap-like nature of the record inevitably leads to the sudden appearance of species and the lack of transitional forms (Bowler 1989). Given this, he posed a strikingly indifferent stance on the appearance of clearly transitional forms found shortly after the first publication of *Origin of Species*. For instance, despite his close ally’s gradual support for *Archaeopteryx* as transitional between reptiles and birds, Darwin included only one timidly phrased sentence about it in later revised editions. Gawne (2015) argues this may have been due to Darwin’s position on species and his desire for more complete sequences (i.e., successions) rather than “missing links” such as those discovered later for early horses (Fig. 3), which Darwin called the “best support for the theory” (p.1082).

Finally, Darwin notably steered clear of applying his theory to human evolution in *Origin of Species* (Darwin 1859) but covered it in depth in his later writings, particularly *Descent of Man, and Selection in Relation to Sex* (Darwin 1871). Part of the explanation was Darwin’s worry that his ideas would be condemned on religious or moral grounds, but it was probably also due to the lack of the sorts of evidence for human evolution that we have today (Tattersall 2009). Neanderthals had been discovered a year before the

Gaps in Darwin's Initial Theory, Fig. 3 The lack of transitional forms was a gap in the evidence to support Darwin's initial theory. Later work, such as Othniel Marsh's fossil horses which showed a progressive

evolution toward a single toe, pictured here, was viewed as important evidence (Gawne 2015, p.1082). (Image: public domain)

publication of *Origin of Species*, and Darwin mentioned them in his later work. The more transitional, ape-like *Australopithecus* was not discovered until the first half of the twentieth century.

Conclusion

This entry focused on gaps in Darwin's initial theory – a theory he co-discovered with Wallace and then elaborated in his 1859 book. Rather than providing an exhaustive account of the perceived and real problems with the work that originated from the scientific community and from society at large, the entry has focused on a sample of gaps chosen for their relevance to evolutionary psychologists and others interested in the evolution of human behavior. In doing so, it should be clear that, although Darwin was fallible and not right about everything, he was a careful and thoughtful scholar, and the criticisms led to a refinement of his ideas where that was possible and necessary. This is in large part, along with its sheer simplistic elegance, why Darwin's early theory remains standing as a centerpiece of current evolutionary biological thought.

Benefits of nursing

Introduction

Nursing is a crucial aspect of maternal care as it helps with the important evolutionary benefit of infant survival and growth. As such, mammals may have evolved to nurse their infants quiet intuitively, albeit bearing some costs (Noonan and Rippeyoung 2011). These costs mainly stem from the fact that mothers require adequate energy to meet both maternal and offspring needs. For instance, some mothers of species that are relatively smaller in size may face higher energy demands due to the large correlation between maternal size and milk output (Ofstedal 1984). Lactation for these mothers may sometimes require energy demands that may be greater than any other time in life (Prentice and Prentice 1988). This may also be the case for species that produce large litters as these mothers would need to have enough physical resources to meet the requirements of the large litter of infants as well as for the mother herself (Rogowitz 1996). However, there may be evolutionary mechanisms that help attenuate these costs and increase the benefits associated with nursing.

However, the costs associated with nursing are sometimes overemphasized. This is suggested to likely stem from implicit misconceptions associated with the parent-child conflict theory (Roulin 2002). Parent-child conflict depicts that parents and offspring may have opposing interests with regard to how much parents should invest in their offspring. However, this may be perceived as if investment in offspring will always come at the cost of parents' somatic energy (Trivers 1974). However, this may not always be the case. For example, in the case of nursing parent-child conflict theory suggests that it may be in the best interest for the lactating mother to wean the offspring sooner while it may be in offspring's best interest to resist weaning for as long as possible. However, nursing the offspring does not typically appear to bear great costs on the mothers' own health especially in typical environments with adequate resources (Roulin 2002).

Calibration of Nursing Based on Environment

Given that newborns across many species require to be nursed when they are born suggests that there may be mechanisms in place to help optimally allocate mothers' energy resources between the energy demands for herself and her offspring. For example, in one study, Rogowitz (1996) showed that the growth rate differences in cotton rat pups of small and large litters were significantly different. These differences were not due to differences in the maternal size of both rat mothers as both mothers were similar in size but rather due to the different energy levels of milk flow from mothers to offspring during lactation. Mothers with the smaller litter had higher levels of energy flow compared to the mothers with the larger litter. What's more, despite the different levels of energy flow, both mothers were found to have adequate levels of energy for their own sustenance. In a similar vein, studies have shown that even the quality of milk changes as a result of the environment, such as the growth rate of the infant (Hinde et al. 2009). These results suggest that the quality of milk flow may be calibrated based on various contextual factors while accounting for mothers' energy requirements. This may be one important factor that allows for the benefits of nursing to outweigh the costs.

Evolutionary Benefits of Breastfeeding

Nursing appears to have broad evolutionary benefits across species. Nursing may help to increase the duration of birth intervals through lactation amenorrhea (not menstruating after giving birth). This is beneficial for helping mothers to focus their investments on the current offspring at least until weaning. Nursing also helps to keep the offspring dependent on the mother as well as proximally close to the mother so that the mother can ensure the infant's nourishment despite any environmental scarcity. This also allows the mother to protect the infant from predators and harm (Sellen 2007). Additionally, nursing is suggested to increase mothers' oxytocin levels

and consequently help facilitate mother-infant bonding.

Allonursing and Benefits of Nursing

The evolutionary benefits of nursing are especially exhibited when examining the literature on allonursing. Allonursing is when female mammals nurse offspring that are not their own and is observed to occur in over 60 species including humans (Roulin 2002). This behavior helps support the theory that the benefits of nursing may greatly outweigh the costs because, if nursing does impose high costs on females, they would not choose to nurse infants that are not their own. Evidence suggests that allonursing helps with inclusive fitness as mothers may typically prefer to nurse an offspring that is not her own, but nevertheless, still choose to nurse a genetic relative compared to a nongenetic relative. This would help the nursing female to propagate her genes. Females may also nurse offspring that are not their own in order to evacuate surplus milk that is not consumed by their own offspring. This may help to reduce pain associated with the pressure in the breast due to excess milk as well as teat infections which can ultimately allow the female to focus the energy on other important somatic functions.

Conclusion

The prevalence and intuitive nature of nursing is an indicator that this behavior is associated with important benefits for the mother and infant. Moreover, the calibration of energy demands for the mother and infant when nursing provides important insights into the underpinnings of maternal investment and behavior. That is, evolutionary mechanisms may be in place so that maternal investment in offspring does not typically come at the cost of maternal health. Mothers who are unable to breastfeed specifically due to deficits in their environment should therefore be provided with the necessary support to help make optimal parenting decisions for themselves and for their infants.

Gender Dysphoria

Devita Singh^{1,3} and Kenneth J. Zucker²

¹Child and Adolescent Mental Health Care, Children's Hospital, London Health Sciences Centre, London, ON, Canada

²Department of Psychiatry, University of Toronto, Toronto, ON, Canada

³Department of Psychology, Western University, London, ON, Canada

Synonyms

Gender identity disorder; Gender incongruence; Transsexualism

Definition

Gender dysphoria refers to a person's discontent and distress with regard to the gender that they were assigned to at birth.

Introduction

As a diagnostic term, gender dysphoria was introduced in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association 2013). It replaced prior diagnostic labels, such as gender identity disorder and transsexualism.

As a diagnosis, the symptoms must be accompanied by clinically significant distress and/or impairment. It is a more narrow construct than terms such as "transgender," "gender variance," or "gender nonconformity."

Phenomenology

Gender dysphoria can have either an early onset (in childhood) or a late onset (in adolescence or adulthood). In the early-onset form, children exhibit a range of stereotypical gender-typed behaviors associated with the other sex (e.g., in peer preferences, toys and activity interests, roles in fantasy play, clothing preferences, etc.), co-occurring with the verbalized desired to be of the other (which is conceptually the most important parameter of the clinical presentation). The sex-typed behaviors associated with gender dysphoria occur in concert, not in isolation, and, therefore, a thorough diagnostic assessment is needed to identify whether a significant pattern of cross-gender behavior is present. For some children, there is an insistence that they are of the other gender. In the late-onset form, the strong desire to be of the other gender is expressed for the first time at some point after puberty, accompanied by significant anatomic dysphoria. For adolescents with gender dysphoria, the DSM-5 criteria do not include concrete behavioral indicators. Instead, the criteria emphasize more abstract phenomenology (e.g., Criterion A6 reads as "A strong conviction that one has the typical feelings and reactions of the other gender. . .or some alternative gender different from one's assigned gender"). Adolescents with late-onset type of gender dysphoria, particularly males, typically do not present with a pervasive pattern of childhood cross-gender behavior or identification and are

often described by parents as stereotypically masculine as children. Sexual orientation (to whom one is attracted to romantically and sexually) is reliably associated with the early- and late-onset forms of gender dysphoria. In males with gender dysphoria, those with an early onset are almost always attracted sexually to biological males (“androphilia”), whereas those with a late onset are primarily attracted to biological females (“gynephilia”), or they are sexually aroused at the thought or image of oneself as a woman (“autogynephilia”) (Lawrence 2010). In females with gender dysphoria, those with an early onset are almost always attracted to biological females (gynephilia), whereas those with a late onset are more variable: many, but not all, are sexually attracted to biological males (androphilia).

Epidemiology

In adults, the prevalence of gender dysphoria has been estimated to occur in 1:14,705 adult males and in 1:38,461 adult females (Arcelus et al. 2015). In children and adolescents, the prevalence is unknown. Using self-identification as transgender, which is a broader term, one study found that 1.2% of high school students in New Zealand answered “yes” to the question “Do you think you are a transgender?” In the United States, a study of adults found that 0.5% considered themselves to be “transgender.” Over many decades, gender dysphoria has been considered more common in males than in females across the life-span, based on referral rates to specialized gender identity clinics. More recently, there has been a shift favoring females, but only among adolescents (for review, see Zucker 2017).

Associated Psychopathology

Many studies have found that gender dysphoria is associated with a range of mental health problems. These problems become increasingly common starting in middle to late childhood. Common problems include depression and anxiety, substance misuse, and suicidality (Zucker et al.

2014, 2016). Some recent studies suggest that gender dysphoria can be associated with an autism spectrum disorder (van der Miesen et al. 2016). Explanations for the presence of mental health problems include an underlying biological vulnerability, the inherent distress that is associated with gender dysphoria, and “minority stress,” i.e., stigma and discrimination.

Developmental Course of Gender Dysphoria

Follow-up of children, adolescents, and adults with gender dysphoria have identified different long-term trajectories. Clinically, this information is of high importance to parents, who will often ask whether their child will pursue a gender transition or whether their child’s gender dysphoria will go away (i.e., desist). Studies of adolescents and adults who have been diagnosed with gender dysphoria suggest that persistence is very common unless it is treated by specific methods (see below). In contrast, follow-up studies of children suggest that persistence is less common, even without any type of treatment. In boys, persistence rates have ranged from 0% to 20% (Singh 2012); in girls, persistence rates have ranged from 12% to 50% (Ristori and Steensma 2016). In comparing the long-term outcome of children with gender dysphoria obtained in prospective studies to retrospective studies of adolescents and adults with gender dysphoria, a notable disjunction with regard to gender identity outcome is observed. While adolescent and adult males with gender dysphoria, particularly those who are androphilic (sexually attracted to biological males), recall a pattern of childhood cross-gender behavior that is consistent with the phenomenology of gender dysphoria, most children with gender dysphoria do not continue to have gender dysphoria in adulthood. How might this disjunction be understood? Children with gender dysphoria have different developmental trajectories, and this leads to diverse outcomes in adolescence and adulthood. Perhaps there is malleability or plasticity in gender identity differentiation early on in development; however, it becomes more fixed as

development progresses into adolescence and adulthood (Singh 2012). Clinical observation and empirical evidence support this idea – persistence of gender dysphoria, including the desire for sex change, is higher among patients assessed for the first time during adolescence and then followed up than among patients first assessed in childhood and then followed prospectively (Singh 2012). In Cohen-Kettenis and van Goozen's (1997) follow-up study of Dutch adolescents with gender dysphoria, the rate of persistent gender dysphoria was 66.6%. This is similar to the percentage of adolescents recommended for puberty-blocking hormonal treatment at the Toronto clinic (Zucker et al. 2011). If we assume liberally that the adolescents recommended for puberty blockers would persist in their gender dysphoria, the persistence rates obtained by Cohen-Kettenis and van Goozen and Zucker et al. in their adolescent samples are substantially higher than that obtained in the follow-up studies of boys with gender dysphoria first referred in childhood.

Follow-up studies of children with gender dysphoria have identified severity or intensity of childhood cross-gender behavior (Singh 2012) and an early social transition (Steensma et al. 2013) as predictive of persistence among biological males with childhood-onset gender dysphoria.

Casual (Etiological) Explanations

Both biological and psychosocial factors have been proposed to explain the origins of gender dysphoria. Biological explanations include genetic factors, alterations in the prenatal hormonal milieu, and, in males, a late fraternal birth order. Concordance for gender dysphoria is more common in monozygotic twins than in dizygotic twins. Structural magnetic resonance imaging studies have examined variations in sex-dimorphic neural structures in both adolescents and adults with gender dysphoria when compared to unaffected males and females. Guillamon et al. (2016) reviewed this literature and found that there was some evidence to suggest that certain

“regions of interest” were altered in people with gender dysphoria. When differences were detected, they were either intermediate between that of unaffected males and females or closer to the “other” biological sex. However, such differences are not always detected: in these instances, the region of interest was no different than that of controls of the same biological sex. Blanchard (2017) reported that adult males with gender dysphoria (restricted to those who sexual orientation was androphilic, i.e., sexual attraction to biological males) were more likely to have older brothers than unaffected males. The explanation for this is that, with each successive pregnancy of a male fetus, there is an antigenic maternal immune response that impacts male-typical psychosexual differentiation.

Psychosocial factors include gender dysphoria thinking about gender identity, an early identification with the opposite sex parent, reinforcement of gender-variant behaviors in early childhood, and traumatic experiences (e.g., sexual abuse) that cause one to feel unsafe vis-a-vis one's birth-assigned gender. In early childhood, it is common for children to have fairly gender dysphoria notions about gender. For children who express gender-variant behavior, this “black and white” thinking might lead some children to believe that because they have interests that are similar to the other gender, then perhaps that means that they should be that gender or that they actually “are” that gender. Because “black and white” thinking is very characteristic of children with an autism spectrum disorder, this has been given as one possible explanation for the co-occurrence with gender dysphoria (Strang et al. 2016). Because most children have their first attachment to their mother, it has been argued that this is one reason that gender dysphoria is more common among boys than girls because they have greater difficulty in shifting their gender-related identification to their fathers or a father figure. In girls, this is less of a problem because initial attachment to the mother makes a same-gender identification less complicated. Early studies of parental response to marked gender-variant behavior in boys indicated that it was common for parents to either view the

behavior as “only a phase” and that the behavior was either tolerated or reinforced (Green 1987).

Therapeutics

Over many decades, a general consensus emerged that psychological or psychiatric treatment of gender dysphoria in adults was not particularly effective, even when the patient desired it. This led to the search for alternative methods to reduce the gender dysphoria. Thus, common treatments nowadays include a social transition to living as the desired gender; hormonal treatment to alter, where possible, the phenotypic markers of the desired gender; and gender-affirming surgery. It is now recognized that in carefully evaluated adults, these treatments lead to a reduction in the gender dysphoria (Coleman et al. 2011).

In adolescents, it is also believed that, in the majority of patients, psychological or psychiatric treatment is also ineffective, again even if the patient desires it. As a result, contemporary treatments include a social transition to living as the desired gender, the use of puberty-blocking hormonal treatment to suppress somatic masculinization (in males) or feminization (in females), subsequent implementation of contra-sex hormonal treatment, and, in adulthood, gender-affirming surgery when it is desired. In carefully evaluated adolescents, this treatment protocol appears to be successful in reducing the gender dysphoria (de Vries et al. 2014).

In children, best-practice treatment is more controversial and less definitive. Some clinicians argue that some form of psychologic intervention can be successful in reducing the gender dysphoria (Zucker et al. 2012), noting, for example, the high rate of desistance, even in the absence of formal treatment (Singh 2012). Others argue for a “watchful waiting” approach (de Vries and Cohen-Kettenis 2012), and some clinicians argue that children should be supported, if not encouraged, to socially transition to the desired gender (Ehrensaft 2012). The differences among these treatment approaches are related to differences in theoretical and philosophical conceptualizations of the origins of gender dysphoria, and,

nowadays, it has become more apparent that parents of children with gender dysphoria differ in which treatment approach they desire for their children. Unfortunately, there is little in the way of systematic studies comparing these treatment approaches, and so various clinical guideline documents recommend a case-by-case decision-making practice in which parents are given as much information as possible in order to make an informed decision about treatment options (Drescher and Byne 2012).

Conclusion

In summary, considerable clinical and research advances have been made over the past several decades in understanding various aspects of gender dysphoria: phenomenology, epidemiology, associated mental health problems, developmental course, causal mechanisms, and best-practice therapeutics. However, much remains unknown. For instance, we still do not understand the process through which gender dysphoria desists or have a thorough understanding of the various factors that interact to influence long-term outcome. The role of therapeutics on long-term outcome also remains unclear. Over the past few years, there has been a substantive increase in professional interest in the well-being and health disparities among children, adolescents, and adults with a minority gender identity. This will, undoubtedly, lead to further accumulation of knowledge with translational benefits for clinical care of patients experiencing gender dysphoria.

Definition

The evolutionary origins of why and how friendship differs as a function of the biological sex of friends.

Introduction

Friendship is a relationship between two people based on mutual liking in which partners provide support to one another in times of need. Because it does not require a familial or formal tie, friendship is typically regarded a nonobligatory relationship of choice. Although individuals often choose to enter into and remain in a friendship, friends are expected to have genuine positive regard and concern and provide emotional and instrumental support to each other (Hall 2012; La Gaipa 1977). Characteristics of friendship are very similar across cultures (Hruschka 2010; Terrell 2015). One of the unique qualities of friendship is that it does not follow tit-for-tat exchange. Rather, friends provide aid and support to one another based on need. This challenges evolutionary explanations for its emergence (Hruschka 2010; Silk 2003).

The expression and expectations of friendship have shown some sex differences (Hall 2011; Reis 1998). This chapter will review two prominent evolutionary accounts of sex differences in friendship (e.g., Geary et al. 2003; Taylor et al. 2000) and examine several evolutionary explanations for the function of cross-sex friendships (Bleske and Buss 2000; Bleske-Rechek et al. 2012; Lewis

et al. 2015). In general, research on friendship from an evolutionary perspective is still in early stages of development, and evolutionary explanations of sex differences in friendships constitute only a small subset of this body of research.

Levels of Friendship

A relationship is “a tie between two or more individuals that is stable over time and across contexts” (Brown and Brown 2006, p. 4). Relationships require mutual and specific acknowledgement, or individuation from a group, and some degree of mutual influence (Hall and Davis 2017). These three defining characteristics of a relationship (i.e., stability, individuation, interdependence) allow humans to effectively and efficiently regulate social, emotional, and material investments in another person in relation to future returns. It is notable that friendship-like bonds among nonhuman primates and other social animals (e.g., dolphins, elephants) share these three definitional properties (Seyfarth and Cheney 2012). Considering the evolutionary origins of friendship, Seyfarth and Cheney (2012) contend that a *relationship* is constituted by the “cumulative memories and emotions created by many previous interactions,” and other group members can recognize its existence (p. 166). The ability to form enduring associations with preferred others and the ability to recognize that bond between others preceded the rise of *Homo sapiens*. Therefore, a relationship, at its most minimal form, is not a uniquely human trait.

Humans can differentiate between various types of relationships. There is a minimum standard for calling someone a friend, but once identified as such, friends are not equal or interchangeable; some are much more valuable than others (Silk 2003; Tooby and Cosmides 1996). Classic research on the friendships of children (La Gaipa 1977) and adults (Weiss and Lowenthal 1975) demonstrates that friendships vary by emotional closeness, expectations and rules of conduct, and nomenclature. Dunbar (1996) has offered an evolutionary-inspired theory of friendship taxonomy and has proffered four categories of friendship: support

clique, sympathy group, friends, and clansmen. The first group (1–5 individuals) may include non-kin best friends but mainly includes immediate kin (Mollenhorst et al. 2014). The sympathy group, which subsumes the support clique, is three times larger (10–15) and may include several good friends or best friends (La Gaipa 1977). The next two groups grow in size by a factor of three (40–50 friends; 120–150 clansmen) (Dunbar 1996). Acquaintances are not friends: adults and children show little difficulty in differentiating a casual friend from an acquaintance (La Gaipa 1977; Weiss and Lowenthal 1975).

One important qualification of contemporary research on the evolutionary origins of friendship is that distinctions between types of friends are rarely so fine-tuned. Many of the unique properties of friendship, especially in terms of positive regard and treatment, are only noticeable at high levels of closeness (Hruschka 2010). Some theories of sex differences in same-sex friendship make explicit distinctions between close friends and group members (e.g., Geary et al. 2003). However, it is more typical that when the concept of *friendship* is referenced, best, close, or very good friends are the object of study.

The Evolutionary Roots of Friendship

Although the particular evolutionary mechanism(s) (e.g., direct fitness, inclusive fitness) enabling the formation of friendships, particularly with non-kin, is a matter of debate (Seyfarth and Cheney 2012; Terrell 2015; Tooby and Cosmides 2008), there is strong evidence that establishing and maintaining friendships offer an array of survival and reproductive benefits, including resource sharing, cooperation, protection, and reproductive opportunity. Due to a high degree of tribal interdependence and the increased likelihood of death following social isolation, the investment of resources in others may have been essential for early human survival (Brown and Brown 2006; Tooby and Cosmides 2008). Heritable traits motivating and regulating the formation and maintenance of social bonds would have been selected for, while traits maladaptive for the individual's bonding

and inclusion would have been selected against (Hruschka 2010; Tooby and Cosmides 2008).

A friendship, therefore, is an adaptive mechanism, enabling the recognition of a uniquely valuable other and streamlining decisions about the type and amount of investment of resources to be made in and to be expected from another, especially among non-kin (Hall and Davis 2017; Seyfarth and Cheney 2012). Although this mechanism enables the development and maintenance of friendships, differentiation among potential friends based upon desirable qualities is another necessary ability. Friends are selected based upon the potential for emotional support and social bonding (Ainsworth 1989; Hruschka 2010) and other valued and observable characteristics (Hall 2012; Tooby and Cosmides 1996). Just as individuals have varying reproductive values as mates, they also have varying association values as friends (Kendrick et al. 2005). This ability to differentiate among others likely had other functions independent of friendship. The ability to estimate the value of particular qualities or behaviors in another person is an important adaptation for the comprehension of social exchange and altruism (Tooby and Cosmides 1996). The ability to differentiate among potential friends based on their association value, the ability to regulate social exchange not based upon tit-for-tat rules, and the ability to recognize and form relationships are all components necessary for the evolution of human friendship.

Sex Differences in Friendship

Two distinct approaches offer mechanisms for interpreting sex differences in the expression of friendships. Drawing from Hartup and Stevens' (1997) recognition of the importance of deep structures of friendship, Hall (2011) argued that ideal friendship expectations define the meaning or essence of friendship. These expectations are the standard upon which new and ongoing friendships are judged (Fehr 1996). This approach embraces the concept that friends differ by association value, and ideal friends possess qualities that yield the greatest benefits. The particular

qualities sought in an ideal friend should differ depending upon the needs of the individual. Biological sex may influence which qualities in ideal friends are most needed. Specifically, sex differences in expectations are more likely to have evolved in circumstances where females and males differ in outcomes needed or desired from friends (Hall 2011). For example, when one type of friendship characteristic offers benefits to or serves the needs of females more than males, females should more highly value these behaviors or qualities in an ideal friend.

Another mechanism that could influence the emergence of sex differences is niche construction (Bahns et al. 2017; Terrell 2015). The preference for friends who are similar based on attitudes, personality traits, and values is a well-established tendency (La Gaipa 1977; Hall 2012; Newcomb and Bagwell 1995). Rather than passively awaiting friendships to form with proximal others, humans seek out and put effort into forming and maintaining friendships with preferred others. The niche construction perspective suggests that humans shape their physical and social environment to be more suitable, agreeable, and adaptive (Bahns et al. 2017; Terrell 2015). Similarity between friends increases time spent in mutually enjoyable activities (Fehr 1996), creates coherence and consistency in friends' interpretation of external events and people (Terrell 2015), and plays a critical role in friendship selection (Bahns et al. 2017). Niche construction is a self-protective and self-gratifying process that is beneficial inasmuch as it facilitates social acceptance and harmony, speeds information transmission, and increases the chances of joint activity accomplishment. Below, both approaches will be considered in conjunction with perspectives of sex differences in same-sex friendships.

Same-Sex Friendships Among Women

In proposing a model for understanding sex differences in stress response, Taylor et al.'s (2000) tend-and-befriend hypothesis also provides an evolutionary explanation for sex differences in friendship generally. Taylor et al. (2000) suggest

the tendency toward a tend-and-befriend response to stress evolved in females due to asymmetric investment in offspring and a need to form and maintain protective female coalitions. The befriending response is marked by the development of affiliation with group members who provide resources and protection for females and their offspring in times of need (Taylor et al. 2000). That is, friends, particularly close friends, offer protection from predators and other humans. These risks were more likely for women due to the likelihood of assault from men and because fleeing responses were constrained by greater responsibility for the survival of offspring (Taylor et al. 2000). Among nonhuman primates and social animals, strong friendship-like bonds between females are much more common than between males. Matrilineal kinship, particularly between mothers and daughters, is "the single most important factor affecting the development of long-term bonds among animals" (Seyfarth and Cheney 2012, p. 160). Furthermore, stronger and more permanent bonds are more frequently found among non-kin female primates than among non-kin male primates (Seyfarth and Cheney 2012). Taylor et al. (2000) suggest that because caring, supportive, and protective friends would be more valuable for females compared to males, sex differences favoring females in emotional support and intimacy should exist. Such evidence is abundant. Females, compared to males, are more likely to cope with stress by seeking emotional support, expect more intimacy and understanding from their same-sex friends, have more emotionally close friendships, and have a few intimate friendships rather than many weak ties.

Evidence supporting females' greater tendency toward using emotional support to reduce stress has shown marked sex differences (Tamres et al. 2002), wherein females seek out, receive, and are more satisfied with social support. The strongest sex differences in coping strategies involved seeking emotional support, particularly for stresses originating from emotional causes (Tamres et al. 2002). Investigating sex differences in ideal expectations of intimacy, emotional support, and empathic understanding from close friends (i.e., communion expectations), Hall (2011) found

a medium-sized difference ($d = 0.388$), which was not moderated by culture. This is consistent with past meta-analysis that demonstrates females' greater behavioral intimacy in friendship (Reis 1998), even as children (La Gaipa 1977). Part of this difference may be due to different types of relationship engagement. The tendency for boys to play in groups and girls to interact in dyads is "perhaps one of the most well-established findings in the children's friendship literature" (Fehr 1996, p. 117). Taken together, as children females prefer same-sex friendships based on dyadic interaction, which likely shapes ideal expectations of communion from same-sex friends and matures into greater intimacy and emotional support for same-sex adult female friends. Compared to men, women experience more intimate and higher-quality same-sex friendships for close friends and less close friends alike (Fehr 1996).

Same-Sex Friendships Among Men

Geary and colleagues (Geary and Flinn 2002; Geary et al. 2003) focus on other factors that may have shaped same-sex friendships among men, many of which are complimentary to the arguments of Taylor et al. (2000). Geary and Flinn (2002) focus on the role of philopatry, which is tendency for females to migrate to another group (e.g., through marriage), compared to males who are more likely to stay in their birth group. Noting that two-thirds of groups are composed of male kin and female non-kin, Geary and Flinn (2002) suggest females were more likely to be among unrelated others compared to males. Therefore, females would be more likely to develop mechanisms of obtaining mutual and reciprocal benefits from unrelated others (Geary et al. 2003). By contrast, male coalitions were more likely to be marked by competition and predominantly nonreciprocal relationships due to associating with hierarchically differentiated male kin. Under these conditions, reciprocity between friends would be a critical component of female-female friendships but less so for male-male friendships.

One implication of Geary and colleagues' argument is that males should seek out

characteristics in friends that might offer benefits within the group and during inter- or intragroup competition or aggression. Within males' social network, friendships reflect a balance of cooperative and competitive behaviors. Because group unity and cooperation is necessary for achieving group-level goals, the stabilizing bonds of friendship were also necessary. In the social environments of men and boys, competition, once resolved, results in a more stable social structure for the entire coalition. Within the group, men and boys might wish to develop friendships with men who are well positioned, well connected, or well resourced. Through the reciprocal bonds of friendship, males can gain access to resources and protection (Geary et al. 2003; Kendrick et al. 2005). In this sense, the ideal male friend would have accessible and valuable resources.

In his meta-analysis, Hall (2011) tested Geary and colleagues' argument: compared to women and girls, men and boys should be more likely to favor resources, prowess, and status from same-sex friends. Identifying these characteristics as *agency* expectations, Hall (2011) found that males are more likely than females to describe ideal same-sex friends as well resourced (e.g., financial resources, physical fitness, social connections) ($d = -0.337$). This difference was not moderated by age or culture. Additionally, Geary and Flinn (2002) suggest that sex differences in intimacy, exclusivity, and emotional support favoring females may have also been influenced by philopatry. If men were more likely to be among male kin, they could count on them to come to their aid with or without friendship. In maintaining larger groups of weak ties, men would not be able to invest sufficiently to each relationship to create expectations of intimacy or emotional support.

Similarities Shaping Differences Between the Sexes

Four characteristics of same-sex friends do not differ by sex and are similar across culture and age: propinquity, homophily, inclusion, and preference for same-sex friends. Propinquity, or physical proximity, and homophily (i.e., similarity

between friends) are identified as the fundamental building blocks of friendship. The lack of sex differences or cultural variation in expectations of homophily (Hall 2011) suggests that niche construction through similarity selection may be a fundamental friendship process that does not vary by sex. Furthermore, inclusion, or the desire to be in the company of and invited by friends, is similar between the sexes (Hall 2011). Among children, friends spend more time together than non-friends primarily because of similar play behaviors and shared activities (Newcomb and Bagwell 1995). Furthermore, there are no sex differences in time spent with friends at various ages (Fehr 1996). Finally, children and adults tend to choose best friends of the same sex across cultures (Borner et al. 2015; Hruschka 2010).

Considered in conjunction with niche construction processes, these four characteristics may play an important proximal role in creating sex differences. Hall (2011) pointed out that inclusion by, time spent with, and preference for same-sex peers is a crucial proximal mechanism for the emergence of sex differences from both an evolved and a developmental perspective. Group-level dynamics are a factor in the evolution of sex difference precisely because of preference for same-sex relationships, socialization, and coalition formation (Kendrick et al. 2005). From a niche construction perspective, cross-cultural and cross generational tendency toward a preference for same-sex friends might arise from a desire to find similar others based on friendship expectations, play and activity preferences, and a shared perspective. A combination of similarity in preference for same-sex friends and a lack of sex difference in the importance of inclusion by friends suggests that sex may be one selection criteria that influences the construction of friendship niches. That is, from a niche construction perspective, preference for similarity in sex of friends and inclusion by friends would likely produce overlapping niches of similarity for sex-linked traits, preferences, and behaviors. These would likely reify sex differences through behavioral reinforcement, as conforming to friendship expectations plays a crucial role in making and keeping friends (Fehr 1996; La Gaipa 1977). That sex differences

in communion expectations grow as the age of the sample increases supports this conclusion (Hall 2011).

Finally, it is notable that the most essential and important characteristics of friendships, such as trust, genuine regard, and loyalty (Fehr 1996; Hartup and Stevens 1997), do not show substantial sex differences (Hall 2011). There appears to be a great deal of cross-cultural similarity in these aspects of friendship and among adults (Hruschka 2010) and children (Borner et al. 2015). Hall (2011) concludes that because less than 3% of the variance in these essential characteristics can be explained by sex, differences are unlikely to be the result of evolved mechanisms. As Hartup and Stevens (1997) argue, there should be few sex differences in the most essential friendship expectations because both sexes seek out, maintain, and find considerable value in trust, commitment, and genuineness in friends.

Cross-Sex Friendships: Sexual Strategies Theory, Risks, and Benefits

Friendships between heterosexual men and women (i.e., cross-sex friendships) are most commonly considered in relation to reproductive risks and benefits rather than stress amelioration or navigation of kin hierarchies. In this section, the risks of cross-sex friendships for individuals in committed romantic partnerships will be considered first, and then the risks and benefits of cross-sex friendships among noncommitted adults will be considered.

For individuals in an existing romantic relationship, especially those with children, cross-sex friends are threatening for two primary reasons: mate poaching or resource sharing (Bleske and Buss 2000; Bleske-Rechek et al. 2012; Lewis et al. 2015). For both men and women, a partner's cross-sex friendship could undermine the existing relationship through sexual infidelity or mate poaching. This threat is warranted by research reporting that one-third of those who had had sex with a cross-sex friend were dating someone else at the time (Afifi and Faulkner 2000). According to sexual strategies theory (SST)

(Buss and Schmitt 2016), one primary risk for men in committed long-term relationships is that paternity probability is not fully knowable. SST would predict that men would feel threatened by their partners' cross-sex friend because it poses a risk of sexual infidelity and would experience jealousy and engage in mate guarding to prevent infidelity. A cross-sex friendship could develop into a romantic relationship, putting men and women at risk of losing their long-term partner (i.e., mate poaching). This also poses risks to the well-being of offspring from the initial relationship, especially if children from the first pair bond are raised by stepparents. According to SST, one of the distinct risks women face when their male partners have cross-sex friendships is resource sharing, especially if the cross-sex friendship develops into a reproductive relationship. Additional partners and/or children diminish the resources available in the initial pair bond and can potentially result in a long-term split of the man's resources between two women and, potentially, two sets of offspring. Although both men and women might maintain a cross-sex friendship as a backup mate, SST would predict that women may be more inclined to seek out a backup mate as a form of insurance if the initial partner is unfaithful or unreliable (Buss and Schmitt 2016). Unsurprisingly, Hruschka (2010) cites widespread cross-cultural evidence of suspicion of cross-sex friendships, typically due to concern for their impropriety and threat to romantic relationships.

The benefits of a cross-sex friendship have also been explored from the perspective of SST (Lewis et al. 2011). Aside from the benefits of friendship in general (e.g., support, trust, genuine positive regard), cross-sex friendships offer valuable insight into the mind of the opposite sex, and, as such, cross-sex friends can become trusted informants and confidants (Bleske-Recek et al. 2012; Sapadin 1988). From the perspective of SST (Buss and Schmitt 2016), this insight might translate to greater access and success in mating, especially if cross-sex friends help each other find partners through friendly introductions or helpful approach strategies (Lewis et al. 2015). Furthermore, men often identify cross-sex friends as

valuable sources of emotional support, intimacy, and self-disclosure, and women often identify cross-sex friends as sources of instrumental support, fun, and enjoyment (Fehr 1996; Sapadin 1988). SST suggests that characteristics valued in a cross-sex friend are similar to characteristics desired in long-term partners. Lewis et al. (2011) demonstrate that cross-sex preferences for friends were similar to cross-sex preference for mates: men preferred female friends who were physically attractive with unrestricted SOI, and women preferred men with more physical prowess and resources.

SST has implications for same-sex friendships as well. Taylor et al. (2000) and Geary et al. (2003) argue that having high status, attractive, and athletic friends has clear implications for mating opportunities for males in hierarchically arranged group. Men might prefer agency characteristics (e.g., status, athleticism) in their male friends, not just for the status it confers within the group but also as those characteristics might increase mating opportunities (Bleske and Buss 2000; Lewis et al. 2015). It stands to reason that through intimacy and emotional support shown with same-sex friends, women are demonstrating characteristics of good parents and committed partners, both of which are attractive traits to men seeking a long-term relationship.

Even among single adults, the challenges of romantic potential and sexual desire complicate cross-sex friendships. Although the taboo of spending time with cross-sex friends has diminished greatly in Western cultures and 92% of young adults can name at least one close cross-sex friend (Halatsis and Christakis 2009), nearly 52% of respondents report being openly or secretly attracted to a cross-sex friend (Reeder 2000). Indeed, cross-sex friendships are a common pathway to romance: two-thirds of men and nearly half of women agreed that friendship could become a path toward romantic or sexual intimacy (Sapadin 1988). Thus, it is very likely that at least one side of a cross-sex friendship has considered the possibility of a romantic or sexual relationship. This attraction is based in reality: friends are accurate when estimating how much cross-sex friends are interested (Koenig et al. 2007), and

attraction in cross-sex friendships is more often mutual than not (Bleske-Rechek et al. 2012). Although romantic attraction seems to be experienced at similar rates by men and women (Koenig et al. 2007), men are much more likely to be sexually attracted to their cross-sex friends, and women are more likely to experience unwanted sexual pursuit (Lewis et al. 2015). Thus, women are more likely to underestimate, and men are more likely to overestimate sexual attraction from their cross-sex friend (Koenig et al. 2007). These findings are consistent with SST in that men are more likely to seek sexual access through cross-sex friendships, and women are more likely to seek backup mates, especially with men with greater long-term mating potential.

Caveats to Cross-Sex Claims

There are two caveats to characterization of cross-sex friendships based on SST: a narrow focus on types of friendships and types of affection in friendship. Sex differences in reported sexual interest, desirable qualities in cross-sex friends, and the virtues of cross-sex friendships are all supportive of SST (Buss and Schmitt 2016). These findings are likely most applicable to young, single adults in Western cultures that allow cross-sex friendships. Like most studies on friendship, these findings focus on primarily emotionally close friendships to the exclusion of many cross-sex friendships that are neither particularly close nor likely to develop closeness in the future. Indeed, some stated benefits of a cross-sex friend, such as self-disclosure or instrumental support or protection, are neither likely nor appropriate in weak-tie friendships, whether same- or cross-sex. Although experiencing jealousy from an emotionally intimate cross-sex partner appears to be normative, being jealous of every cross-sex casual friend is likely rare. Furthermore, close cross-sex friends are relatively rare in adult samples, compared to college-aged samples, especially between friends of the same age. As such, threats from cross-sex friends are likely infrequent among adult as they have few cross-sex friends generally. Finally, cross generational, familial,

and ceremonial friendships exist commonly across the world, albeit much less so in Western countries (Hruschka 2010; Terrell 2015). Cross generational, inherited or ceremonial, familial friendships connect friends' offspring in an inter-generational web of relationships that approximate kin (Hruschka 2010; Terrell 2015). In the United States, such friends take on familial names, such as aunts, uncles, or cousins. Many such friendships are cross-sex but are unlikely to be explainable from the predictions of SST. Lewis et al. (2015) concur that the adaptive challenges and benefits of cross-sex friendships likely change over the life course. Human friendship psychology may be sensitive to such changes, yet the research on these types of friendships is scarce.

Considering cross-sex friendships from the perspective of sexual access and opportunity may overstate the role of sexual desire in cross-sex friendships. Many cross-sex friendships do not report sexual tensions or interest, and friends make active efforts taken to avoid perceptions of sexual or romantic interest. In intimate cross-sex friendships, the social attraction and genuine regard are often so valuable to friends; they actively avoid even the appearance of sexual interest. Furthermore, A Western cultural lens might confound of friendship and sexual interest to a degree not shared cross-culturally. In Hruschka's (2010) review of friendship across cultures, he posits that Western cultures have only recently strongly linked companionate love (i.e., affection as close friends) with sexual desire and long-term union. He persuasively argues that the feeling of bonding, connection, and closeness can develop independently from public, ritualized unions producing children and from sexual relationships. Hruschka (2010) cautions against sexualizing the expression of affection between friends in Western and non-Western cultures alike. Applying his argument to cross-sex friends, companionate love between cross-sex friends may be reduced sexual desire or romance due to a narrow, Western understanding of both marriage and friendship. If companionate love between friends were more acceptable culturally and marriage was not a primary source of friendship for adults, then cross-sex friends might be regarded with more

acceptance and less suspicion. Hruschka (2010) concludes that cross-sex friendships are not clearly understood from an evolutionary perspective.

Conclusion

The role that sex of friend plays in friendship from an evolutionary perspective has been informed by several prominent theories. More research is needed to test these theories and to better understand variation between cultures, ages, and levels of emotional intimacy in the expression and development of friendship.

Definition

Gender schemas are cognitive structures that organize information about gender.

Introduction

Scientists have long sought to explain gender differences in a number of phenomena – for instance, in relationships, interests, activity level, and communication styles. Cognitive approaches, including gender schema theory, have been proposed to address the development of such gender differences by explaining the cognitive processes underlying gender typing.

As discussed here, gender consists of the individual identification with and societal roles assigned to male and female groups, which differs from sex, the biological components of humans such as reproductive systems and secondary sex characteristics. Thus, gender typing (i.e., matching a gendered prototype) is the process by which individuals become differentiated by

gender in their behaviors, preferences, and cognitions. Although biological predispositions and consistent socialization influence this process, a cognitive approach suggests that cognitive structures like schemas also contribute as important mechanisms of gender typing. Gender schemas, then, are cognitive organizers of information related to gender (e.g., traits, behaviors, appearance) that motivate future information processing and behaviors. Thus, gender schema theories address how schemas are used in processes that create gender differences.

Early Theory Development

Although the cognitive revolution in psychology influenced the development of gender schema approaches, cognitive approaches to understanding stereotyping have been evident in the literature for many years. During the 1970s and 1980s, interest in social schemas emerged in psychology, and cognitive approaches, including gender schema theory (GST), were informed by these more general social psychological studies. Interestingly, three gender schema theories were proposed within 1 year, and other researchers were also exploring their use even before these theories were published (for review, see Martin 1991). These theories (here all considered GST) share the ideas that (a) individuals form gender schemas and there are variations in these schemas, (b) individuals actively process information using their gender schemas, and (c) these schemas have specific effects on memory and behavior. However, the variations of GST differ in emphasis. Here we discuss the two most well-developed and researched approaches: the Bem (1981) version of the theory that emphasized variations in the salience of gender schemas in adults and the Martin and Halverson (1981) version of the theory that focused on developmental issues, functions of schemas, and resulting biases associated with using schemas.

Features of Bem's Gender Schema Theory

Sandra Bem approached the issue of variations in gender typing in adults and from her research

proposed a theory based on the idea of gender schemas (Bem 1981) and then later extended this to children (Bem 1983). Bem proposed that, because much of global society organizes based on gender, individuals develop a specific schema to facilitate the processing of gender-related information. For example, individuals learn commonly stereotypic things like what personality traits, activities, appearance, and behaviors are considered appropriate for each gender (e.g., women are expressive, men are dominant). Bem suggests that an individual's self-concept (i.e., how one perceives the self) becomes assimilated into the gender schema, which means that the information categorized as relevant to their gender group is information relevant to themselves.

Bem wrote that processing information in this way is associated with a number of outcomes, including using gender schematic information as a guide for what to learn and how to behave, such as developing skills and engaging in activities only appropriate for their gender. Gender schemas are prescriptive: individuals can evaluate themselves (and their adequacy as a person) in terms of how they match their gender's characteristics (as stored in their gender schema). Thus, a gender schema becomes an internal motivating factor to conform to gender norms, which can contribute to a readiness to develop in gender-typed ways.

Furthermore, the focus of the theory is not on the content of the schemas but instead on the availability of gender schemas and how this varies across individuals. The frequent use of the gender schema contributes to a tendency for information to be processed in a gendered way or to see the world through a gendered lens (Bem 1993). Bem described the tendency of having highly accessible schemas as schematicity or the degree to which one uses gender schemas in their reasoning. That is, gender is highly salient for some people and not as much for others (i.e., aschematic). Aschematic individuals are less bound by the proscriptions of their gender schemas and embody traits associated with members of each gender group (not just their own, as would highly schematic individuals). Bem called this androgyny, meaning that they have both positive masculine and feminine characteristics,

which was considered advantageous for healthy development (Bem 1974).

Features of Martin and Halverson's Gender Schema Theory

Martin and Halverson (1981) also proposed a gender schema theory, which was published in the same year as Bem's and complemented her work. Both theories sought to provide cognitive explanations for the development of gender differences; thus, both highlighted the role of schemas in the processing of gendered information. They also both posit that gender schemas serve to not only organize information but also to motivate an individual to conform to schematic norms associated with their own gender group.

The Martin and Halverson gender schema theory, however, has a few key differences from Bem's. First, there is a developmental focus to this theory such that as individuals' gender identity develops, gender schematic processing becomes more salient; after learning to identify with a gender category, gender typing emerges more strongly. In addition, Martin and Halverson proposed a slightly different mechanism for developing an own-gender schema. Rather than assimilating the self-concept into the gender schema, Martin and Halverson proposed that there are multiple schemas including a superordinate schema that contains information about what traits and activities are appropriate for each gender and an own-gender schema that contains detailed plans of action for carrying out own-gender appropriate activities. Children then self-socialize; that is, they seek information appropriate for their own gender while discounting other-gender information. That is, the own-gender schema guides their behavior and knowledge of the other-gender suggests what is not appropriate. This also highlights the intergroup focus of this theory, such that information processing is divided along social group lines (in-group and out-group) – in this case, gender lines.

A central theme in this version of GST is that children develop gender schemas and then these schemas are influential as they guide their behavior and thinking to be consistent with their schemas (Martin et al. 2002). The superordinate

schema promotes memory for stereotypic consistent information and directs behavior toward stereotypic consistency vs. inconsistency. For instance, individuals tend to better remember information consistent with these schemas (male firefighter) than inconsistent information (female firefighter). The own-gender schema promotes memory for in-depth information and facilitates complex behaviors aligned with one's gender.

Experimental studies confirm that children are more likely to interact with, attend to, and remember information consistent with their own gender. These studies involve using novel, unfamiliar, and nongender-typed toys, giving them labels suggesting a gender preference (e.g., "this is a toy that boys really like"), and observing children's behavior and assessing their memory for the toys and their labels. The same toy labeled as a toy boys like was played with more by boys and remembered better than a toy labeled as a toy girls like; when labels were reversed for other children, boys avoided that toy. Also, in other studies, a novel toy liked by a boy can be made less appealing by saying that it is a toy girls like to play with. A number of studies have demonstrated these patterns (for review, see Martin et al. 1995).

Gender schemas also influence the social judgments individuals make about others. One line of research assessed the judgments that children made about peers. Although there are developmental patterns in these findings, generally children use information about gender (and if they are older, about children's gender-based interests) to make inferences about how much they would like these children, and they use gender schemas to make predictions about how gender-typical these children's interests are. Younger and older children tend to believe they will like other children of the same gender better than children of the other gender.

Gender schema theory also holds that individuals will develop broader "gender theories" that they apply when they lack information. For instance, they are likely to infer that someone the same gender as themselves will share similar interests, values, and beliefs, and that they will likely follow gender stereotypes. Research studies illustrate the way gender theories lead to

differentiated behaviors and expectations: a girl who says she would really like a particular novel toy also thinks other girls will like it but boys probably will not. These theories may help explain the strong tendency of individuals to show same-gender preferences and to thus gender segregate.

Holding gender schemas also leads to a number of distortions and biases. The Martin and Halverson version of GST gave a detailed description of these biases. One bias is memory distortions that change information toward the direction of the schema. For instance, a child seeing a picture of a woman police officer may later remember that information differently, more stereotypically, by remembering that the police officer was a man. These kinds of distortions make changing schemas a challenge and may explain why programs designed to reduce gender stereotyping are often ineffective (Martin and Halverson 1983).

Newer research on this version of gender schema theory has focused on variations in gender schemas to better understand within gender differences. Tomboys, girls who identify as girls but enjoy counter-stereotypic activities and interests, do not appear to hold to traditional gender schemas. However, assessments of their schemas show that they hold somewhat more broad schemas, more inclusive ones (that acknowledge more exceptions), but that they still hold their behavior to be consistent with these schemas (Martin and Dinella 2012). Even more recent, researchers are in the process of exploring the schemas of socially transitioning children – children who feel they are a different gender than the one they were born – and these children conform to the schemas they hold (Olson et al. 2015). In some ways, these studies provide the strongest evidence of the power of individual's self-socializing since they often experience socialization pressures to conform to their natal gender assignment.

Summary

Both versions of GST were developed to better explain questions of interest to gender researchers: why do individuals stereotype others,

why do individuals engage in gender-typical behaviors and relationships, and what accounts for variations in these behaviors? The cognitive approach adopted by GST assumes that individuals are actively involved in processing, attending to, remembering, and interpreting information about gender from their social worlds, and for individuals with salient gender schemas, they are actively searching for information about gender.

Although these two versions of gender schema theory have slightly different focuses, they integrate well to explain the phenomenon of gender typing. They both emphasize the cognitive structures present in processing gendered information; they also highlight the active role of the individual in shaping their learning through differential attention and motivation associated with own-gender-appropriate information. Although gender schema theory focuses on the cognitive structures and processes behind gender typing, its tenets are compatible with other theoretical explanations like social learning and biologically driven perspectives.

Applications to Evolutionary Psychology

The principles of gender schema theories complement work by evolutionary psychologists in many ways. Given the infinite amount of information available to be processed, humans have evolved to create cognitive systems to narrow and simplify cognitive processing through directed attention, encoding, and memory, thereby reducing cognitive load. For example, we form schemas to make information storage and retrieval more efficient and guide future information processing. This includes developing schemas to categorize individuals and characteristics into social groups – by age, by race, or by gender. Also, as we have evolved to attend to and encode cues relating to gender, gender schemas are efficient methods for storing this information.

The categories into which information is sorted (and thus the “titles” of the schemas) and the information contained in these schemas are dependent on what is adaptive to learn in a specific context. This information is often related to

the affordances posed by individuals in certain social groups. Because social groups, like gender, have many affordance implications, it is adaptive to have easily accessible information about the groups that are functionally relevant within a culture. For example, in a culture that strongly emphasizes gender group differences, knowing what interests, preferences, or characteristics to associate with someone of a certain gender helps an individual know what to expect from interacting with them. In addition, although this varies by history and culture, knowing how to fill the prototypical role of one's own gender can be adaptive for many reasons, such as ensuring continued parental care and support, gaining necessary social skills from positive peer interactions, and attracting a desirable mate.

Conclusion

Several gender schema theories were independently developed, and they share a number of similar features including the focus on people being actively involved in processing information about gender. Gender schema theory also elucidates the cognitive processes behind gender typing; individuals organize information by gender and focus especially on learning things considered to be appropriate for their own gender. Cognitively organizing information by gender and selectively encoding own-gender information has implications for individuals' skill development, academic achievement, and even career choice. Important future directions for applying this theory include understanding gender schematic processing of gender nonconformity and similarities in gender schemas for cisgender and transgender individuals. Cognitive approaches do not dismiss the social, biological, or evolutionary contributions to gendered patterns but instead offer a complementary perspective.

Definition

The General Intelligence Factor (*G*) describes the covariance that exists among species-level aggregates of cognitive performance, first described by Reader et al. (2011). The upper-case *G* has been employed in subsequent publications to differentiate this construct from that which exists in the correlations among individual differences in performance on cognitive ability measures (the

lower-case *g*-factor). There exists debate about whether *G* and *g* are one and the same constructs, the resolution of which has considerable implications for evolutionary models of general intelligence.

Introduction

Reader et al. (2011) were the first to identify a *G* factor in the associations among various primate species aggregates of indicators of cognitive performance. Since this publication, subsequent work has elaborated the empirical (Fernandes et al. 2014) and theoretical (Burkart et al. 2016) underpinnings of the construct.

Review

Presented here is a review of Reader et al. (2011) and three subsequent publications, which build on this work. These papers have advanced both the theoretical and empirical foundations of the *G* construct.

Reader, Hager, and Laland (2011)

A common view in the animal cognition literature is that different taxa exhibit unique, specific cognitive abilities tailored to their niche, and thus their intelligences cannot be compared on a common metric. According to this line of thought, differences in cognition between species are mainly of kind, not degree. An alternative view is that, even though species-specific adaptive problems may lead to the existence of some modular abilities, some overarching domains may also exist (e.g., social intelligence; Whiten and Byrne 1988) each involving many specific abilities. Going a step further, a general processing mechanism adapted to deal with evolutionarily novel problems may be a locus of difference in performance among taxa, with different tasks being expressions of the same latent general intelligence.

Experimental, laboratory studies comparing several mammal and bird species, reviewed by Reader et al. (2011), support the existence of

such a common factor, with taxa exhibiting high performance in certain tasks tending to do well across others. However, relying only on experimental data to test the existence of the *G* factor is a limited approach, as laboratory tests can be species biased (i.e., unfair to particular species), may not reflect natural conditions (i.e., being ecologically invalid), and are available for few species. As a much-needed alternative to this approach, Reader et al. (2011) collated counts of cognitive flexibility-related behaviors in the wild from the primatological literature to examine the existence of *G* in the primate order. In this *tour de force*, the authors compiled extensive data for 62 primate species for five categories: tool use, extractive foraging, innovation, social learning, and tactical deception.

Factor analyses involving these five measures confirmed the extraction of a *G* factor, explaining up to 65% of their variance. The importance of this effect is compounded by two observations: (1) this estimate is higher than most found for the extremely replicable general intelligence (*g*) factor among human individuals (50%); and (2) the *G* factor appears extremely robust to controls for many potential confounds (e.g., phylogenetic or geographic inertia, group and population size, brain and body size, exclusion of data from captive specimens). Apes, on average, exhibited the highest scores in *G* and prosimians the lowest, but high *G* scores evolved independently in capuchins, baboons, and macaques. As expected, neuroanatomical size measures appeared to underlie the species differences in cognitive ability. Moreover, as social learning was found to be an integral part of the *G* complex, it is likely that this domain-general capacity permitted the evolution of cultural transmission and complexity.

Fernandes, Woodley, and te Nijuenhuis (2014)

Fernandes et al. (2014) conducted further analyses of the cross-species dataset of primate cognitive abilities compiled by Reader et al. (2011). The results of this study indicated that *G* (the term first having been introduced in this study) has had a more important role in primate cognitive evolution than previously thought. This is suggested by the observations that (1) the size of

species differences in cognitive abilities was found to be larger for abilities that are more central to the *G* factor (i.e., cognitive functions that share more variance with others); (2) less *G*-loaded abilities are more phylogenetically conserved (i.e., have undergone less recent evolution); and (3) they have evolved at lower average speeds. It thus appears that cognitive flexibility-related behaviors have been more salient to positive selection pressures if not modularized in primate phylogenetic history. This was especially the case in the evolution of tool use proficiency, a capacity that may have permitted inceptive niche construction.

Burkart, Schubiger, and van Schaik (2016)

Psychometric studies of human intelligence have distinguished between *G*, a single factor extracted from population-level cognitive ability indicators, and *g*, an intelligence factor calculated based on individual-level scores. Evidence for *g* in non-human species has been found in multiple examinations of cognitive abilities in various avian and mammalian taxa (Galsworthy et al. 2014). In some of these studies, *g* explained 40% of the performance variance, was positively associated with neuroanatomical volume indicators (e.g., overall brain size), and was heritable. A similar pattern was found in nonhuman primates, with *g* explaining 48% of performance variance in a sample of rhesus macaques (Herndon et al. 1997). More recent analysis with chimpanzees has found a single heritable intelligence factor (Hopkins et al. 2014; Woodley of Menie et al. 2015).

Despite the evidence supporting the underlying existence of *g* and *G* in nonhuman species, studies extracting a single intelligence factor across species based on individual-level scores (i.e., mixed studies), have not been that successful. For example, comparisons across primate taxa, including studies contrasting the scores of 23 individuals from four great-ape species were unable to extract *g* (Hermann and Call 2012). Similarly, another (Amici et al. 2012) study examining the scores of 99 individuals (seven different primate species) did not locate either *g* or *G*. According to Burkart and colleagues (2016), one of the issues of mixed

studies is that the effective sample is not the total number of subjects, but rather g is calculated based on the number of individuals within species, and G is estimated based on the number of species. Consequently, this statistical inconsistency increases the amount of noise in the analyses. Furthermore, Burkart et al. argue that mixed studies do not take into consideration domain-specific adaptations across species; these differences are predicted to modify the mean score for some tests but not others, weakening the correlations across test performance.

Woodley of Menie, Fernandes, te Nijenhuis, Peñaherrera Aguirre, and Figueredo (2016)

Similar to Burkart et al. (2016), Woodley of Menie et al. (2016) acknowledge that the mixed design does not take into account difference in factorial characteristics between species. Thus, the absence of measurement invariance hinders the adequate estimation of g in pooled samples of individuals from different species. Floor and ceiling effects are also proposed as factors affecting measurement invariance. Thus, tasks relatively simple for one species may be unsolvable for another. The presence of ceiling and floor effects is usually examined according to the statistical distribution in performance. Moreover, specialized abilities are considered to be particular to each species and are predicted to have weaker loading in a single factor.

Woodley of Menie and colleagues proposed that mixed designs could estimate g , if the differences across species are larger on tests with a higher proportion of shared variance, but not in cases where the variation in species performance is uniform. To test these predictions, the authors used a combined dataset of chimpanzee and human children performance on various tasks used to measure intelligence. As hypothesized, children outperformed chimpanzees on more g -loaded tests. However, by sequentially removing from the analyses tests with the smallest coefficients of variation, and correlating the vector of task g -loading with the difference in performance between species (d), the correlation between g and d increased inversely to the number of tasks retained. These findings indicate that differences

across species are indeed concentrated on g and that this is likely therefore the principal source of G . However, this is only apparent when examining tasks that allow enough within-species variation for both species being compared.

Conclusion

The G factor of primate cross-species differences, first identified by Reader et al. (2011), has yielded much in the way of subsequent theoretical and empirical investigation. Many of the insights gleaned from research into the construct could be applied to the task of identifying similar G factors from other groups of taxa where individual differences g factors have been identified within species, such as birds and the nonprimate mammals.

Familial disease; Gene disease; Genetic disorder;
Genetic mutation; Inherited disease

Definition

A missing, extra, or irregular component of the genome that can be inherited, can occur spontaneously, or can be caused by the environment.

Introduction

Genetics, just as every other aspect of science, has seen significant advances in recent years. The understanding we have obtained from these genetic advances has enabled genetic mapping and the early discovery of genetic abnormalities. With this new understanding comes a plethora of questions. These advances have also yielded a necessity for the psychological and social aspects of behavior to be incorporated into the realm of human biology. To understand the evolution of psychology, as it relates to genetic abnormalities, we will discuss the history of genetics, the basics of genetics and genetic abnormalities, and the involvement of psychology and its benefits for those with genetic abnormalities.

The History of Genetics

The genetics that is discussed, observed, manipulated, and studied today has its origins in the teachings of Aristotle and his ideologies regarding the creation of life. His teachings explained that we are each a mixture of our parents' traits with the father supplying the life force and the mother supplying the building blocks (Schwartz and Sharpe 2006). For many centuries his theory remained unquestioned, until the research and memoir of Gregor Mendel in 1866. While his research was published, it did not make an imprint on genetics or heredity until its rediscovery in the 1900s. Several researchers, such as De Vries, Bateson, Johannsen, Morgan, Watson, and Crick, helped rocket Mendel's laws to the forefront of biology. It was Mendel's laws that taught the world about heredity and how inheritance follows particular patterns; his work with pea plants led to the understanding of traits and genetics that we have today (Gayon 2016; Durmaz et al. 2015).

Genetics

To fully understand genetic abnormalities, we must first understand the basics of genetics.

Genetics is the term used to describe the study of genes and heredity among organisms. Genes are the microscopic nucleotides of deoxyribonucleic acid (DNA) that make up the 23 chromosomes. A zygote inherits a gamete cell from each parent; these gametes each contain only one set of chromosomes which is combined to make 23 pairs. On each pair of chromosomes exists two copies of each gene, one inherited from each parent. Genes are the determinants of traits; there are three different types of traits, polygenic, pleiotropic, and Mendelian. Polygenic traits are traits that involve many genes; pleiotropic traits are multiple traits that are affected by one gene; and Mendelian traits are traits that are solely attributed to one gene. An allele is either dominant or recessive and can impact the way a particular trait is presented in an individual. Each individual's genetic makeup is unique, and the combination of genes and chromosomes determines both their genotype and phenotype (Gayon 2016; Durmaz et al. 2015).

Evolution and Psychology

As previously discussed, Gregor Mendel provided the foundations for genetics and how traits come to be. The ideas of evolution, natural selection, and mate selection come from the research and discoveries of Charles Darwin. Darwin's work created the foundations for evolutionary psychology. Darwin and Mendel were not privy to each other's discoveries; but, the ideologies of the two come together for us to fully understand the evolution of genetic traits and how they are passed on to offspring (Buss 2009; Dewsbury 2009).

By merging the discoveries of Mendel and Darwin, we can now study how genetics change within a population. Population genetics is the study of how populations of species change genetically over time, leading to their evolution. The principles of population genetics attempt to explain how genetics and evolution influence each other. Allele frequency, one of the elements that most strongly impacts population genetics, describes how often alleles appear in the genetic sequences of a certain population. Alleles, more

frequent in the population, are more likely to be passed on to offspring, whereas less frequent alleles can be left behind in the process of evolution. There are five factors that can impact the frequency of alleles (Clark 2001; Lowe and Allendorf 2010):

1. **Natural Selection:** This factor is based on Darwin's idea of natural selection, survival of the fittest. Within natural selection, the alleles that are the strongest, or most adaptive, become more frequent in the population (Clark 2001; Lowe and Allendorf 2010).
2. **Sexual Selection:** This factor again comes from Darwin's idea of nonrandom mating. Certain individuals are more sexually attractive to mates than others because of specific traits they possess. Therefore, alleles of most successful maters will have a higher frequency. Similar to sexual selection is the idea of artificial selection. New scientific advances now allow individuals to decide which alleles they want passed on to their offspring, leading to the presence of more attractive alleles within the population (Clark 2001; Lowe and Allendorf 2010).
3. **Genetic Drift:** This factor is attributed to random chance and has no attribution to the adaptivity of a particular allele. In certain instances (e.g., natural disasters), a sample of a population may be lost or isolated, leading to a difference within the alleles of the population (Clark 2001; Lowe and Allendorf 2010).
4. **Gene Flow or Migration:** This factor describes how migration changes allele frequency by introducing individuals with different alleles into a genetically different population (Clark 2001; Lowe and Allendorf 2010).
5. **Mutation:** This factor has to do with the mistakes that happen in the copying process of DNA. Some errors can be favorable and are passed on through mating, leading to the presence of favorable alleles to become more prevalent in the population's gene pool. Other errors can lead to deformation or disease or have other negative consequences. These unfavorable alleles are often less prominent (Clark 2001; Lowe and Allendorf 2010).

For the purpose of this article, the factor that we are most interested in is mutation. These mutations are what we call genetic abnormalities.

Genetic Abnormalities

The research of genetic mutation, by Herman Muller, and genetic analysis, by Tjio and Levan, made it possible to identify abnormalities within the genetic structure of chromosomes that are attributed to congenital defects. These abnormalities within the genetic structure can be caused by deletions, duplications, repetitions, modifications, translocations, and the absence of genes on any one of the chromosomes. The genetic location of the abnormality will determine the effect it will have on the individual (Gayon 2016; Durmaz et al. 2015).

Thousands of genetic abnormalities have been discovered by researchers; some are considered harmless, and others can be debilitating or life-threatening. There are four classifications of genetic abnormalities; single-gene disorders, multifactorial disorders, chromosomal disorders, and mitochondrial disorders (Funk and Wagnalls Corporation 2018). Single-gene disorders are classified as such because it is the mutation of one gene that results in the presence of this particular class of disorders (Bates 2005; Psychological and Social Implications 2010). Multifactorial disorders are characterized by the variety of factors that lead to their development; multiple errors in gene mutation and environmental factors contribute to these disorders. The genetic makeup of these disorders can often be described as a predisposition for a multifactorial genetic disorder (Bertella et al. 2007; O'Neill and Kennedy 1998). Chromosomal genetic disorders are classified by genetic variations of partial or entire chromosomes. Lastly, mitochondrial disorders are the rarest form of genetic abnormality. Mitochondrial disorders are caused by a genetic mutation of the mitochondria that inhibits its production of energy (Cao et al. 2018).

How are specific genetic abnormalities selected through evolution? As previously mentioned when discussing allele frequency, the most frequent alleles are often the most prominent in a

population. Genetic abnormalities, while not always adaptive, can also become present in a population and passed on or selected for a particular reason or environmental factor (Gall 2011; Abrams 2009).

Psychological Aspect of Genetic Abnormalities

Evolution as we know is the process of change over a period of time; and just as humans have evolved, the brain has evolved along with it. The brain was no longer used simply for survival but also for learning, intellect, and conscious awareness. However, the brain itself is not immune to being impacted by the genetic mutations and abnormalities that occur during the evolutionary process. However, the genetic abnormalities within the brain can have characteristics that do not necessarily present themselves physically, but behaviorally. It is through these behavioral impacts that genetic abnormalities can attribute to psychological deficits. These deficits are largely due to the complexity of the human brain (Buonomano 2011; Solso 2003).

In his book, *Brain Bugs* (2003), Dean Buonomano described the evolution of the brain as “new structures were placed on top of older functional structures, leading to redundancy, waste of resources, unnecessary complexity, and sometimes competing solutions to the same problem” (pp. 12). As complexity increases so does the capacity for error, in this case, genetic abnormalities occur that lead to changes within the cognitive processes of the human brain. These errors lead to deficits that impact cognitive function such as Down syndrome, Alzheimer’s disease, developmental delays, learning disabilities, mental retardation, and many more (Genetic Disorders 2018; Buonomano 2011; Psychological and Social Implications 2010).

Another bridge between psychology and genetics is through the diathesis-stress model. The diathesis-stress model states that individuals have predisposing factors within their genes. However, the way that an individual interacts with their environmental stressors determines if and when they will meet criteria for a specific

diagnosis. Diagnoses such as schizophrenia, major depressive disorder, and bipolar disorder have strong genetic components; but, without the “right” stressor, an individual with a genetic predisposition can live their entire life without experiencing the psychological effects of these disorders (Anderson and Nickerson 2005).

Other Psychological Effects

The evolutionary aspect of treating genetic abnormalities turns to psychological treatment as a means of improving quality of life for individuals that suffer from them. In previous years, due to the lack of understanding of these disorders, patients with genetic abnormalities were not faced with the opportunity to improve behavioral, interpersonal, cognitive, or other nonmedical aspects of their lives. However, relatively recent advances in genetics allow for the treatment of the individual from a psychosocial standpoint, which considers their mental health as well as psychical well-being (McDaniel 2005).

Additionally, a new dilemma of genetic testing comes into play with the newest genetic advances and the capacity of genetic mapping. Genetic testing yields answers to previously unknown aspects of our lives. There are obvious benefits and disadvantages to genetic testing that may leave individuals in a panic and wondering if knowing the definitive truth about their genetics is really better than embracing the unknown. The answers provided by genetic testing may lead individuals to experience negative self-esteem, anxiety, or depression or have negative impacts in their interpersonal relationships (McDaniel 2005).

Benefits of Psychological Treatment

Psychological treatment when dealing with psychosocial effects of genetic abnormalities may be beneficial. Genetic testing, while controversial, can benefit the people around the individual with the disorder to effectively understand a support them. Psychoeducation may be beneficial when provided for both the individual and the family,

allowing them to ask questions and know what to expect regarding the disorder. Behavioral limitations of the individual may be addressed along with proper decisions about their well-being and overall quality of life. Additionally, intellectual, behavioral, and cognitive function may be improved through psychotherapy, yielding an effective style of coping, allowing the processing of emotional responses, developing an open avenue for family communication, and stimulating a positive environment and a greater quality of life for the individual (Otter et al. 2018; McDaniel 2005; Jiménez et al. 2018).

Conclusion

In conclusion, genetic abnormalities can originate through a variety of different methods: natural selection, sexual selection, genetic drift, gene flow, or mutation. Regardless of how abnormalities arise their impact on the individual is apparent. These abnormalities can not only physically affect the individual but also cognitively, impacting the overall fitness of the individual. Additionally, the proper support and psychological intervention may help with the psychosocial effects of the genetic abnormalities that may come our way and aid in the positive interpretation of information that may be hard to handle. Future research can be done to determine the most effective forms of psychotherapeutic treatment.

Genetic and Prenatal Components of Homosexuality

Jacques Balthazart

GIGA Neurosciences, University of Liege, Liege, Belgium

Synonyms

Biology of homosexuality

Definition

The biological mechanisms that determine, at least in part, same sex versus opposite sex attraction.

Introduction

Homosexuality, the sexual attraction to members of the same sex (as opposed to heterosexuality) is commonly assumed be controlled by social interactions (constructivism), early learning (ethology/

behaviorism), or blockade of sociosexual development (Freudism). Recent research in genetics or endocrinology has shown that genes and hormones, acting pre- or immediately postnatally, contribute to a large extent, if they do not completely determine, the sexual orientation of a subject.

Homosexuality can be viewed as a sex reversal of sexual preferences since homosexual males are sexually attracted by the sex that is normally the target of women's attention and vice versa. Substantial evidence suggests that the mechanisms that control the development of sexually differentiated characteristics also participate to the determination of sexual orientation.

Hormonal Influences

In mammals, sex chromosomes (XX in females and XY in males) determine in early life the sex of the gonads (ovaries or testes), and subsequently, testosterone produced by the embryonic testes determine the development of primary sexual characteristics (penis vs. clitoris, sperm ducts vs. vagina and uterus). The work of Young and colleagues (Phoenix et al. 1959) and hundreds of studies that followed extended this principle of sexual differentiation of morphology to behavior. Independent of the chromosomal sex, embryonic exposure to high male-typical concentrations of testosterone, or its metabolite estradiol, leads to the development of a subject with a "male brain" who will in adulthood be able to display male-typical sexual behavior in response to testosterone but will be unable to display female-typical behaviors in response to estradiol plus progesterone. Conversely the absence of exposure to these high testosterone concentrations during early life will produce female subjects unable to display male typical behaviors in response to testosterone but producing female behaviors in response to estradiol and progesterone. These organizational effects of testosterone take place during a critical period of development and are afterwards irreversible.

Multiple experiments in several species of mammals (mostly rodents) suggest that sexual

partner preference develops under similar hormonal influences somewhat independently of a direct action of the genetic sex. Subjects exposed during early life to high concentrations of testosterone (or estradiol) will display male-typical partner preferences and be sexually attracted to and try to have sexual interactions with females, whereas subjects developing in the absence of testosterone will be sexually attracted to males, a female characteristics.

Two types of arguments indicate that this type of early hormonal mechanism is implicated, to some degree at least, in the control of sexual orientation (see Balthazart 2011; LeVay 2011 for reviews). Firstly, human pathologies that are associated with substantial modifications of the embryonic endocrine environment are associated with increased incidences of homosexuality. For example, girls affected by congenital adrenal hyperplasia, a condition that exposes them to high concentrations of androgens before birth, display a significantly increased incidence of homosexuality even if their endocrine status is pharmacologically corrected after birth. This is also the case of girls born from mothers who had been treated during their pregnancy with the synthetic estrogen diethylstilbestrol in the hope of preventing spontaneous abortions. Note also that conversely, XY embryos who were exposed to male-typical concentrations of testosterone before birth will generally display in adulthood a male-typical sexual identity and orientation even if they were raised as girls from birth for different reasons such as malformation or accidental destruction of the penis leading to sex reassignment and surgical correction of genital structures during the first postnatal weeks.

Secondly, numerous studies have compared the expression of sexually differentiated traits that are known to be controlled, at least in part, by embryonic testosterone in homosexual and heterosexual populations and found that these traits are on average feminized in homosexual men and/or masculinized in homosexual women. These traits include morphological characteristics such as the relative length of the second and fourth finger, the relative length of long bones in the legs, arms, and hands, or the volume of several brain

structures such as the suprachiasmatic nucleus, the anterior commissure, or the interstitial nucleus of the anterior hypothalamus number 3. Several physiological characteristics that are affected by prenatal testosterone also show similar differences between homosexual and heterosexual populations including aspects of the inner ear physiology (otoacoustic emissions), the estrogen feedback on the secretion of luteinizing hormone, and the brain activation by male or female odors as detected by positron emission tomography or magnetic resonance imaging.

Together these data point to a role of pre- or perinatal endocrine influences on the development of sexual orientation. It is clear however that the research does not suggest at this point that sexual orientation is completely determined by hormonal factors since correlations between sexually differentiated traits and homosexuality only explain a limited part of the variance and no endocrine pathology results in a complete reversal of sexual orientation in all subjects.

Genes

Even if embryonic steroids were fully determining sexual orientation, this would only move the quest for the mechanisms one step further; the next question would then be why is steroid action atypical in some subjects resulting in a homosexual orientation? External events such as an enduring exposure to stress are known to inhibit fetal testosterone secretion in rodents, and based on epidemiologic studies on boys born in Berlin during World War II, it has been claimed that chronic embryonic stress could cause male homosexuality. No other study has however been able to confirm this finding.

Exposure to endocrine disruptors that are now widely present in the environment is also of great concern, but this theoretical idea has not received any experimental support so far, and such evidence will obviously be difficult to obtain due mainly to the long latency between exposure and expression of sexual orientation.

Many studies have demonstrated that male and female homosexuality are partly heritable

therefore suggesting the existence of genetic influences (Ngun et al. 2011). These influences can in theory be relatively direct (presence of genes affecting sexual orientation) or mediated by hormonal mechanisms (changes in the synthesis or catabolism of embryonic sex steroids, alteration of steroid receptors, etc.). Within a family, if a son is gay, 20–25% of his brothers will share this orientation, compared to 4–6% in the whole population. Similarly, lesbians have a greater probability than heterosexual women of having a homosexual sister. This increased incidence could obviously reflect communality of educational or social factors, but the comparison of true (monozygotic) and false (dizygotic) twins allows to a large extent to reject this interpretation: concordance of sexual orientation is systematically higher in true than in false twins who had to a large extent the same postnatal experiences. Based on multiple studies analyzing this concordance, it seems that in social conditions typical of Western societies, approximately 50% of the variance in human sexual orientation would be explained by genetic factors.

However, the quest for the genes that are influencing sexual orientation has met with limited success so far. Studies of the incidence of male homosexuality in family lineages indicated that this homosexuality is largely transmitted through the maternal lineage: a gay man has a higher than average probability of having gay relatives in his maternal uncles and cousins than on the paternal side. This finding that was replicated several times was suggesting that genetic influences on male homosexuality were transmitted via the X chromosome (the only one systematically inherited from the mother), and a highly publicized study by Dean Hamer and colleagues identified in 1993 a linkage of male homosexuality with the telomeric region of the X chromosome called Xq28 (Hamer et al. 1993). This linkage has been replicated in three more studies including a very recent one published in 2015 that was based on a large sample of several hundred subjects (Sanders et al. 2015). The specific gene(s) located in Xq28 that seem(s) to affect sexual orientation has(ve) however not been identified, but it is intriguing to note that the gene coding for

the androgen receptor coregulator MAGE-11 is located in this chromosomal domain and thus potentially controls sex steroid action at the receptor level. This gene could provide the link between hormonal and genetic mechanisms.

The putative genetic controls of sexual orientation are however quite complex: linkages with other chromosomal loci have more recently been identified (Ngun et al. 2011), and evidence is progressively accumulating indicating that epigenetic mechanisms differentially affect gene expression in homosexual and heterosexual subjects (Rice et al. 2012; Ngun and Vilain 2014).

It is also interesting to note that the relative incidence of homosexuality in a family increases by approximately 33% for each older brother born to the same mother. This effect has been established and replicated several times based on the study of thousands of gay men, and thanks to this huge sample size, it has been possible to demonstrate by partial regression techniques that the increased incidence of homosexuality does not relate to the age of the mother or father, nor to the number of older sisters or younger brothers, nor to the total number of boys present in the family (Bogaert and Skorska 2011). The only possible interpretation of this effect is based on the progressive development in mothers bearing a male fetus of antibodies that would interfere with the normal development of the male brain.

Conclusion and Societal Impact

It is at this point impossible to ignore that various biological factors including sex steroid hormones, genes, and epigenetic mechanisms affect in a prominent manner sexual orientation. It is also clear that none of these factors is able to explain by itself all cases of homosexual orientation. There are possibly different forms of homosexuality that are controlled by different factors (differential controls in gays and lesbians, in more or less masculine/feminine men and women), or alternatively different hormonal and genetic factors must interact to result in a homosexual attraction, or finally these biological factors do not, by themselves, determine sexual

orientation but rather modulate the probability of acquiring a homo- versus heterosexual orientation, and this orientation will then develop in interaction with unidentified influences of the postnatal environment. Recent studies from the laboratory of Melissa Hines in Cambridge, UK, have shown in this context that, contrary to control girls, girls who were exposed to abnormally high concentrations of androgens in utero due to congenital adrenal hyperplasia do not copy the use or preference for toys that were declared or shown to be typical for their gender (Hines et al. 2016). One can speculate that sexual partner preference could develop under similar interactions of pre- and postnatal influences.

Even if multiple questions still remain unanswered, it appears obvious that sexual orientation is heavily influenced by a variety of biological factors. It is a complex behavioral trait that can be voluntarily accepted and publicly assumed, but it is not only a matter of free choice. Therefore ostracism and persecution have no rational foundation and should be altogether abandoned.

Definition

There are at least two views of genetic determinism, one of which no scientist or intellectual of any significance has ever believed to be true, but which is nonetheless widely known, and another which is novel and is proposed and defended in this entry. The first, received, conception maintains that genetic factors alone are causally responsible for the behavioral traits/outcomes of human beings. The second, novel, conception maintains that *variation* in at least some socially salient human behavioral traits/outcomes is caused primarily by individual and social genetic, rather than nongenetic environmental, factors (at least in adults).

Introduction

Genetic determinism is usually construed as the idea that “an organism’s phenotype is determined by genotype alone” (Sesardic 2005, p. 14). Though genetic determinism in this sense could apply to any life-form, the substantial controversy surrounding the notion predominantly or

exclusively concerns its application to humans. Moreover, the supposed claim that human *behavioral* rather than physical traits/outcomes are genetically determined has engendered virtually all of the cultural and academic rancor associated with the concept of genetic determinism, with one behavioral trait in particular, intelligence (whether presented in terms of IQ or general intelligence [g]), having proved especially incendiary in this context (see, e.g., Glad 2008).

The trouble is that no serious scientist or intellectual has ever endorsed genetic determinism as just defined, and thus it is *prima facie* mysterious how the concept has garnered so much attention. In considering the history of the idea of genetic determinism, this entry aims to explain the likely drivers of the controversy that has attended the concept. But the central goal of this entry is found elsewhere. Specifically, it attempts to define and defend a tenable genetic determinist view in light of the best relevant scientific evidence currently available. As it happens, the expectation or hope that nongenetic environmental factors, particularly those that are at least to some extent under human control, chiefly or entirely determine (variation in) key human behavioral traits/outcomes is almost certainly false. There may be political and moral reasons for wanting this environmental determinist thesis to be true. But those do not change what the germane empirical data indicate, even if they do inspire resistance to the implications of those data.

History

It is probably impossible to find any noteworthy scholar or scientist who thought or has thought that genetic factors alone determine phenotypic traits. Neven Sesardic goes further, averring that “there is literally *no one* who ever subscribed to genetic determinism” (2005, p. 14; emphasis added). When one attempts to study the history of the thesis of genetic determinism, only two things are typically found: (1) social scientists and humanists – hostile to biological modes of explanation of human behavioral phenomena – employing “genetic determinism” and cognate terms to

smear and misrepresent those who have attempted to study the genetic (and sometimes other biological) bases of human behavior (hereafter, the latter individuals are referred to as “hereditarians”); and (2) hereditarians explicitly distancing themselves from the idea of genetic determinism, hoping to avoid attacks from their “biophobic” peers. In most academic discourse that includes it, “genetic determinism” is thus nothing other than a term of abuse.

John Glad (2008) makes a similar point, maintaining that “unalloyed genetic determinism is . . . partly an invention of egalitarian environmentalists, who attribute [the view] to their opponents in an effort to discredit them” (p. 62). Helmuth Nyborg (2003) copiously documents the “demonization” (p. 443) of modern and contemporary scientists who have reported substantial genetic influences on behavioral traits/outcomes in humans, and also suggests that “fear that genetic determinism is morally wrong” significantly motivates support for competing environmental determinist models (p. 480; it is worth noting that Nyborg also highlights the tendency of critics of hereditarianism to pit it only against “an extreme version of the environmental paradigm,” rather than “admit to even a moderate form of genetic determinism” [p. 480]). Sesardic (2005) argues at length against the many distortions and caricatures of hereditarian research that a number of philosophers of biology, and some scientists, have advanced, most prominently Philip Kitcher and Daniel Dennett (to his credit, Kitcher [1985] at least shows awareness that hereditarian researchers deny that they are genetic determinists [p. 8]). In the course of his critical assessment of these anti-hereditarians, Sesardic makes clear that they have inveighed against their targets for moral and political, not just scientific, reasons, at least at times (see also Cofnas 2016). Kitcher (1985), for example, assails the psychological research of Cyril Burt for its supposed role in creating the allegedly harmful British 11-plus exam (Sesardic 2005, pp. 42–44), lamenting the purported fact that this exam, and the “misguided science” (which is to say biobehavioral science applied to humans) underpinning it, wrongfully “mangled” the “aspirations” of children (p. 11), perhaps especially “working-class and lower-middle-class” ones (p. 1). (These claims of

Kitcher's are either false or misleading [see Sesardic 2005, pp. 42–44], and it should be noted that he is in a long line of academics who have unjustifiably maligned the work of Cyril Burt [see Tredoux 2015 for a defense of Burt].) He also condemns “sociobiology” as “potentially damaging to the cause of social justice” (Kitcher, 1985, p. 7).

In view of the foregoing, one has the impression that critiques of hereditarianism, including bad faith efforts to connect it with the “ludicrous” (Sesardic 2005, p. 14) idea of genetic determinism, have more to do with concerns about adverse *consequences* that may emanate from hereditarian scientific inquiry than anything else. To be more precise, it is the fear that hereditarianism might justify or engender social and/or political evils that signally motivates anti-hereditarianism. This fear seems to have originated from fairly recent historical events. Feltham (2017) observes that “[t]wenty-first century collective Western consciousness remains haunted by Nazism and the Holocaust”: “the Holocaust exerts a massive moral and symbolic pull towards the concept of human rights and their enshrinement in international law ... [Contemporary leftist causes] unconsciously gain moral traction from implied associations [of perceived enemies] with Nazi persecution, eugenics and threatened extermination” (p. 17). In other words, horror at the prospect of another Holocaust or a similar moral catastrophe has compelled militant opposition to anything that can be associated, however tenuously, with the worldview of German National Socialism, including virtually all of rightist thought and politics. Since National Socialists saw the characteristics of human groups and individuals as determined to some extent by heredity, and because this belief was part of National Socialists' basis for practicing eugenics, some understand any attempt to relate genetics to important existential outcomes, for groups or individuals, as tending intrinsically to genocidal politics. Some anti-hereditarians have indeed associated their critical targets with National Socialism and related ideologies, typically without any basis for doing so (see Nyborg 2003).

But the notion that hereditarian beliefs have had an exceptional role in mass political killing

is not congruent with the record of history. It is a plain fact that people understood hereditary factors to be causally associated with interindividual behavioral variation and social inequality for many centuries before the emergence of National Socialism; Plato, for example, considered intelligence to be substantially heritable, a belief that partly motivated his support for eugenic practices (Ruse 1985, p. 135). Many or most of the historical societies in which such basically hereditarian beliefs predominated were, to be sure, violent and cruel, largely due to challenging existential conditions typical of preindustrial life (Woodley of Menie et al. 2017a) and to related genetic factors (Frost and Harpending 2015), but they did not all participate in the mass murder of innocents. Moreover, the totalitarian Marxists of the Soviet Union alone, not to mention other genocidal and democidal Communist regimes, e.g., of China, Cambodia, Vietnam, and North Korea, killed many more civilians, indeed millions more, than the National Socialists, despite strong commitment to environmental determinism (see Courtois et al. 2001; Pinker 2003). (It is worth asking why few contemporary Western intellectuals think that Lysenkoism and other environmental determinist models of the bases of human behavior promote genocide while almost all of the same people believe that hereditarian thought does so. It should be recognized that the ideas about human behavior of many prominent figures [living and dead] in Western academia, for example, Stephen Jay Gould [see Sesardic 2005, p. 191], are about as environmentalistic as those of the murderous Soviets. The hypocrisy of such people in accusing hereditarians of inciting genocide and the like, simply by virtue of their hereditarianism, is therefore striking.) These facts are almost never mentioned in discussions of the supposed potential to instigate violence latent in hereditarian thinking. But even more seldom broached is the fact that the largely liberal Allied powers were potentially responsible for the violent deaths of around two-and-a-half million “ordinary Germans” in the wake of World War II (MacDonogh 2009). It would appear, then, that other elements of National Socialist society must be invoked to explain its genocidal activities, for the mere fact that it

maintained a hereditarian ideology seems neither necessary nor sufficient.

Moralistic protest against hereditarianism thus should be seen for what it is: a rationalized effort to deform and control science in accord with prejudice against biobehavioral ideas. Interestingly, many involved in this effort are quite unvarnished about their moral and political biases against hereditarian (and sometimes more broadly biological) perspectives on human behavior. An example comes in the form of a paper from a team of sociologists, which investigates attitudes in the American population about the “importance of genes for understanding individual differences in a series of broad domains: physical illness, serious mental illness, intelligence, personality, and success in life” (Shostak et al. 2009). The piece fails to mention the fact that variation in outcomes in *all* of the “domains” considered is under substantial genetic control (e.g., Bouchard 2004; Clark 2014; Kujala 2011; Panizzon et al. 2014; Riemann and Kandler 2010). Indeed, the article shows no meaningful interest in whether genetic factors *are* important determinants of variability in these outcomes, but instead expresses much anxiety, through a survey of the works of other sociologists, about the potential for hereditarian explanatory paradigms to “justify existing inequalities” and “promote ‘essentialism’” (Shostak et al. 2009, p. 78). This concern about the possible deleterious ramifications of hereditarian ideas strangely begs the question against hereditarianism – for it seemingly assumes that social and ideological factors (e.g., hereditarian beliefs) can greatly contribute to the generation and sustainment of certain unwanted social outcomes (e.g., inequality), but that genetic factors cannot. Hereditarianism is evidently assumed to be wrong out of hand. In asking why this is done, one may find an answer from the authors, who are helpfully forthright in acknowledging the source of this rather nonscientific, politicized orientation to the subject of hereditary influences on human behavior: “Some analysts have argued that beliefs in genetic causation are likely to resonate most strongly with the world views [*sic*] of people who occupy socially privileged positions or who have conservative political orientations . . . social scientists who favor progressive social change may

[therefore worry about the implications of genetics research]” (p. 78). The claim that those on the academic left are generally wary of and hostile to hereditarian thought fits, as has already been shown, with the history of opposition to the idea of genetic determinism. And it is also supported by empirical work on the relationship between political outlook and views about the relative importance of environmental and genetic factors to behavioral outcomes, which has found that academics and (more so) leftist academics, especially those in disciplines such as sociology that are dominated by leftists (Carl 2015), are inclined to genetic denialism or skepticism of various sorts (Geher and Gambacotra 2010; Horowitz et al. 2014).

Hereditarianism and Existential Ideals

A further ideological basis for resistance to hereditarianism is not so much moral or political as it is existential. In Western societies especially, a common aspiration is to direct the course of one’s life free, to the extent possible, from the constraints and influence of unchosen circumstances (Rubin 2015). The metaphysical thesis of causal determinism, well known in the free will debate, has been interpreted as a threat to such hopes for self-formation (Kane 1996), insofar as it posits that everything that occurs in the universe inevitably results from prior states of the universe coupled with the laws of nature, leaving apparently no room for ultimate human agency. But crucially, the thesis of causal determinism is compatible with, say, the possibility that human nature and each individual person’s life are open to radical change: it holds simply that whatever change in fact occurs ineluctably occurs, given prior states of the universe and natural laws. Hereditarianism, particularly strong forms of it that posit that differences in key human life outcomes are largely under genetic control, is actually far more threatening than mere causal determinism to the aforementioned hopes for autonomy, for it indicates that such life outcomes are typically stable, perhaps bordering on immutable, at least in relation to the outcomes of others. To take an example, if social status is settled mostly by genetic factors (and

evidence suggests that it is; see Clark 2014), and if, because genetic, these factors are not open to relevant change for any given individual, then ordinary Western expectations to rise in one's social hierarchy may be largely irrational. One is left most rationally expecting "more of the same," which is perhaps disturbing to those seeking to improve their lot in life. Kitcher (1985) appears to fear precisely this possibility, insofar as he warns about the potential of hereditarian ideas to "mangle" people's "aspirations" (as noted above).

But it should be asked how good *unrealistic* expectations are (see Sesardic 2005, p. 180). Surely hereditarianism is potentially beneficial if it frees people of unreasonable hope and helps them to adopt more sensible goals given their abilities and dispositions. Those who have internalized a culture that values social mobility and self-formation may be inclined to uncritically accept Kitcher's portrayal of hereditarianism as dangerous. Yet this inclination might be little more than an artifact of moral blindness issuing from that same culture, an inability to appreciate the harms that may come of refusal to accept human biological limitations, and thus is no reason to drop the hereditarian paradigm. (Nevertheless, if variation in cultural values is under strong genetic control, which is highly likely, efforts to change such values by way of argument may often be futile.)

The Case for (Revised) Genetic Determinism

In setting out to defend a more reasonable conception of genetic determinism, it is first necessary to be clear about what that conception posits. Revised genetic determinism is qualified with respect to both the traits/outcomes and individuals to which it applies and the causal power that it ascribes to genetic factors. Moreover, it does not make claims about the degree to which traits/outcomes are "caused by" genetic factors, but rather about the degree to which trait/outcome variation is under genetic control, and does not claim that variation in all traits/outcomes is mostly under genetic control. It would be absurd to argue that heredity is the primary determinant of differences

in *all* human behavioral traits/outcomes, since some of these, e.g., short-term memory, exhibit almost no heritability, i.e., interindividual trait/outcome variation due to interindividual genetic variation (Woodley of Menie and Fernandes 2015). Further, revised genetic determinism applies only to *adult* humans, given that the heritability of at least some behavioral (and other) traits/outcomes rises into adulthood. Thus revised genetic determinism maintains only that variation among adults in certain significant behavioral traits/outcomes is primarily genetically determined, those being general intelligence, executive functions (i.e., cognitive controls of behavior), life history speed, and social status. (This is not to imply that there are no other important behavioral traits/outcomes variation in which is substantially genetically determined; rather, it is simply taken to be part of the definition of revised genetic determinism that it only concerns the four traits/outcomes just listed, a choice explained in the following.)

The focus is on these traits/outcomes because they are so widely believed to be extremely important for the quality of human lives, which is why research on them has generated so much controversy in the behavioral sciences (the case of general intelligence, mentioned above, is illustrative here). Whether and to what degree, say, differences in individual preferences for ice cream flavor are genetically determined is not an issue on which anything meaningful seems to hang. But it is of obviously profound importance whether and to what degree variation in general intelligence is genetically determined, since this trait substantially influences a number of critical life outcomes (Strenze 2015), e.g., educational attainment, and because the extent to which differences in it are malleable carries a number of major implications for social policy. Therefore, the fact that the ambit of revised genetic determinism is quite narrowly circumscribed barely reduces the importance of its claims relative to original genetic determinism.

With preceding sections of this entry in mind, it should be apparent that revised genetic determinism does not hold that genetic factors are the exclusive determinants of variation in any

human behavioral trait/outcome (there is not sufficient evidence to support the belief that individual differences in any such trait/outcome are fully genetically determined at this point in time, at least). When writing about the greater relative contribution of genetic as opposed to (nongenetic) environmental influences to differences in behavioral phenotypes and outcomes, terms such as “primarily,” rather than “entirely” or “completely,” are therefore used.

A point that merits emphasis and elaboration is that revised genetic determinism is concerned with the degree to which trait/outcome variation is genetically determined, not the degree to which traits/outcomes are “caused by” genetic factors. It is unclear whether the latter issue will ever be elucidated. In discussions of the relative effects of genes and environmental factors on phenotypic development, it is often remarked that without “environmental input,” a genome would only make a “damp spot on the carpet” (quoted in Sesardic 2005, p. 14). This statement suggests the obvious point that neither genes nor environmental factors are in isolation sufficient to produce a phenotype. Indeed, given their interdependency, it is no clearer whether genes or environments contribute more to the development of some phenotype than it is whether kerosene or sparks contribute more to a fire resulting from their interaction, a matter that quickly leads to probably irresolvable philosophical debates about the nature of causation itself. Moreover, it is apparent that what is at issue in controversies surrounding “genetic determinism” has nothing to do with the overall degree to which a trait/outcome is “caused by” genetic or environmental factors. It does not seem likely that many people would take umbrage at the idea that the ontogenetic development of intelligence is overwhelmingly “genetically determined,” *if* this were paired with the claim that all *variation* in intelligence among persons is environmental in origin. The (mostly leftist) critics of hereditarianism clearly have been concerned with the determinants of trait/outcome variation, given that their primary moral-political goal is typically the reduction or elimination of inequality among humans, not the causal bases of trait/outcome development *per se*,

despite their frequent (mis)use of the “genetic determinism” smear. Nevertheless, such critics *are* wont to observe that certain traits that are clearly under strong genetic control exhibit no variation in healthy human populations and thus would exhibit no heritability in standard behavior genetic studies (e.g., the number of chambers of the heart). This is sometimes presented as if it were a devastating critique of the usefulness of behavior genetic research in uncovering the role of genes in trait/outcome development; but since behavior genetic studies never have been intended to measure the “overall” genetic determination of traits/outcomes, but instead the relative contributions of genetic and environmental variation to trait/outcome variation, this line of attack is simply confused (see Sesardic 2005, pp. 28-33 for a more detailed treatment of this issue).

Crucially, difficulties for any effort to establish the “overall” degree of “genetic determination” of phenotypes do not apply when analyzing the causes of phenotypic *variation*. Since phenotypic, heritable, and environmental variation are quantifiable, statistical analyses can reveal how these variables associate in the case of any particular trait/outcome; one can establish, for example, how much phenotypic variation remains after environmental variation has been controlled statistically or via study design, and thus how much phenotypic variation may be due to variation in heritable factors (such controls will be imperfect, but will nonetheless offer insight into the relative contributions to phenotypic variation of heritable and environmental variation). (That is to say that holding other putatively causally relevant variables constant allows assessment of the potential causal effect of an uncontrolled variable on another variable; in hypothetical studies of the “overall” genetic determination of traits/outcomes, this is seemingly impossible, as genetic and environmental factors contribute to phenotypic development in all cases, and so neither class of factor can be completely controlled statistically or via study design so as to assess the isolated effect of the other.) In light of such analyses, one can determine, for example, the percentage of phenotypic variation for which heritable variation accounts. Such findings then

can be evaluated alongside competing hypotheses and relevant bodies of evidence to determine which causal claims about the respective roles of heritable and environmental variation in producing phenotypic variation are best supported.

But it must be understood that what is classified as trait/outcome variation due to heritable variation in traditional behavior genetic studies does not necessarily indicate the effects of genetic variation alone. Traditional (quantitative) behavior genetic studies do not involve measurement of the effects of individual genetic variants on phenotypic variation (molecular behavior genetic studies aim to do this, however). Instead, they attempt to determine how the phenotypic similarity of individuals associates with environmental variation and genetic relatedness. For instance, a behavior genetic study may examine the phenotypic similarity of monozygotic (or “identical”) twins, who are (usually) genotypically identical, raised in distinct environments. If such genotypically identical individuals tend to exhibit high levels of phenotypic similarity across sufficiently variable environments, then there is apparent evidence that genetic factors have greater control over phenotypic variation than environmental ones. In this standard behavior genetic study design, however, anything that contributes to similarity in the phenotype under investigation of monozygotic twins raised apart should register as a “heritable” source of phenotypic variation. Conversely, any factor that contributes to dissimilarity of the phenotype under investigation of monozygotic twins raised apart should register as an “environmental” rather than a heritable source of phenotypic variation. It is known that in some cases, monozygotic twins are not in fact genotypically identical – one twin may carry mutations that the other lacks (Liu et al. 2018). Mutations are of course a potential genetic source of variation in a phenotype of interest, but if they are not common between monozygotic twins, they will not contribute to the “heritable” component of phenotypic variation in standard behavior genetic studies. By the same token, monozygotic twins raised apart may have environmental factors in common that raise their phenotypic similarity, but these would register as “heritable” sources of

phenotypic variation unless they were accounted for in an appropriate way. While one should be aware of these caveats, it must be stressed that there is little reason to doubt that the heritability coefficients of traditional behavior genetic studies, which, again, indicate the percentage of phenotypic variation due to heritable variation in some population, overwhelmingly reflect the degree of genetic determination of phenotypic variation, and thus “heritable” and “genetic” are often used interchangeably in behavior genetic research. As this entry will discuss at greater length shortly, efforts to find environmental contributions to phenotypic variation that “mimic” heritable variation have not been generally successful (see, e.g., Woodley of Menie et al. 2018).

Given all of this, what can be said in favor of revised genetic determinism? The point of departure here is the substantial behavior genetics literature finding that, among individuals, variation in heritable factors (likely genes) primarily accounts for variation among adults in the four central traits/outcomes listed above. IQ, for instance, is consistently found to be 70–80% heritable by adulthood (Plomin and Deary 2015), with general intelligence, or *g*, having an even higher heritability of 86% (Panizzon et al. 2014; corrected for measurement reliability, Panizzon et al.’s data indicate that *g* is 91% heritable [Woodley of Menie, te Nijenhuis and Murphy 2014]). The factor underlying executive functions may be as much as 99% heritable (Friedman et al. 2008). Life history speed, reflected in the Super-*K* factor – which is superordinate to personality and (mental and physical) health, as well as various other behavioral traits/outcomes such as relationship stability, communitarian attitudes, and insight, planning, and control – is 68% heritable (Figueredo et al. 2006; note that life history speed subsumes executive functions, but the latter cluster of behavioral phenomena nevertheless has been listed as if it were a separate trait, given its unique importance in shaping human life outcomes, even among life history traits – for example, executive functions underlie the critical behavioral factor of self-control). And social status, over the course of centuries and in multiple societies, appears to be about 50–80% heritable

(Clark 2014; it should be noted that in the foregoing work, Clark does not employ standard behavior genetic methods to reach his estimates, but he nonetheless provides ample evidence for the high heritability of social status; however, Clark and Cummins (2018) present further and even higher quality evidence that variation in social status is under strong genetic control).

These findings alone might appear to vindicate the revised genetic determinist view. But efforts have been made to explain such findings away, to show, in other words, that behavior genetic studies of the kind cited above have not ruled out environmental determinism (i.e., the view that environmental factors primarily or exclusively determine variation in critical human behavioral traits/outcomes). One common argument to that effect stresses that behavior genetic studies are only informative about the degree to which genetic and environmental factors explain variation in some trait/outcome *within* whatever population is studied. Indeed, to say that intelligence is 80% heritable is allegedly to simply assert that 80% of the variation in intelligence in a *particular* population is due to variation in genetic factors in that same population. Therefore, it is supposed to be difficult or even senseless to extrapolate from behavior genetic studies to broader claims about the extent to which any particular trait/outcome “in general” varies among people due to genetic variation. Further complicating the “generalizability” of behavior genetic findings is the possibility that heritability estimates at the population level are not informative about heritability at the individual level (the latter would “capture the degree to which a given trait is reliably transmitted across generations” [Woodley of Menie et al., 2015, p. 6]). Finally, and consistent with earlier discussion, critics of hereditarianism sometimes stress the fact that traditional behavior genetic studies merely report *correlations* between *apparent* sources of phenotypic variation and measured phenotypic variation. Given this, these critics are quick to observe that *apparent* heritable sources of phenotypic variation could in fact have no direct causal connection to phenotypic variation (see, e.g., Turkheimer 2016); to reiterate, standard behavior genetic studies do not isolate probable causal

effects of individual genes, but rather estimate the degree of phenotypic variation due to variation in environmental and heritable (widely thought to be genetic) factors generally (though efforts may be made to ascertain the relative importance of additive and non-additive genetic effects and of “shared” and “non-shared” environmental effects – this entry will return to the latter topic). For example, the seemingly high heritability of IQ could reflect the mere fact that people who are highly genetically similar or even identical (identical twins) will tend to have very similar appearances. If appearance substantially influences treatment by others, and if treatment by others substantially affects IQ, then the apparent high heritability of IQ may reflect hidden gene-environment correlations (associations between genetic factors and environmental exposures) that, once properly understood, would indicate that IQ variation is under stronger environmental than genetic control.

These objections to revised genetic determinist conclusions drawn from behavior genetic research are either misleading or just incorrect, however. First, the claim that the individual-level heritabilities of traits/outcomes cannot be estimated is simply false. Woodley of Menie et al. (2015) developed a novel method by which such heritabilities can be estimated and found that, at least for the Super-K factor and related traits and factor structures, these heritabilities are broadly consistent with population-level heritability estimates in standard behavior genetic studies and are roughly the same in the USA and Sweden. Thus there is respectable evidence that population-level heritability estimates correspond to the degree to which traits/outcomes are “reliably transmitted across generations” (Woodley of Menie et al. 2015, p. 6). Second, there are good reasons to be skeptical about the insistence that the heritability of a trait/outcome “in general” cannot be derived from relevant available evidence. For it to be true that we could not make this derivation, the heritability of whatever trait(s)/outcome(s) is at issue would have to vary non-negligibly across populations or subpopulations in different environments, thereby indicating that, perhaps by way of environmental effects on gene expression, environmental factors can appreciably

modify trait/outcome heritability (or at least it would have to be shown that there is no compelling evidence suggesting that environmental factors *do not* have this effect). But the preponderance of germane data gives no reason to believe that environmental effects are so potent, or at least no reason to believe that these effects are *typically* so potent. The facts that IQ is almost always found to be highly heritable by adulthood and that this has been observed in many different populations the world over suggest that intelligence exhibits *developmental homeostasis*, i.e., the tendency of the development of a phenotype to be largely insensitive to environmental and even some genetic variation (Sesardic 2005, pp. 75–80, makes the same essential point). Consistent with these findings, studies have generally found that variation in socioeconomic status is unrelated to the heritability of IQ, and that there are no known environmental interventions by which to reliably and lastingly raise IQ or (especially) *g* in healthy individuals (Protzko 2015; Woodley of Menie et al. 2018). Further to this point, variance in intelligence has not meaningfully changed over long periods of time in which enormous improvements in material quality of life and concomitant reductions in health and material wellbeing inequality (Rindermann 2018) have occurred (Rowe and Rodgers 2002). This is inconsistent with the idea that variation in IQ is to a substantial degree a result of inequality in health and material wellbeing, which environmental determinists seem to often believe.

Social status, or rather the heritable dispositions and behaviors that interact with social environments and have the effect of producing individual differences in social status, seems to be developmentally homeostatic as well. Clark's (2014; see also Clark and Cummins 2018) research offers excellent evidence for this view, insofar as it indicates not only that the heritability of social status is roughly the same in a number of different societies with substantially different cultures and standards of living – e.g., China, Chile, Japan, Sweden, and the USA and UK – but also that the heritability of social status has hardly changed over time. In fact, the heritability of social status was, if anything, slightly *lower* (at times) in preindustrial England than in modern

Sweden, even though the latter is widely extolled for its progressive political and economic culture. England experienced almost no change in the heritability of social status from approximately AD 1300–2000, despite “the Industrial Revolution of the late eighteenth century ... the political reforms of the nineteenth century ... [and] the rise of the welfare state in the twentieth century,” among many other highly significant social, cultural, technological, and economic developments (Clark 2014, p. 87). It is striking that social status, which is seemingly not biological in the way that, e.g., height is, but rather depends on complex interactions between individuals and their sociocultural environment, saw no meaningful change in its heritability over seven centuries in England during which massive and supposedly relevant environmental changes took place. Critics of behavior genetic studies, who expect that environment strongly modifies the heritability of important traits/outcomes, would predict substantial alterations in the heritability of social status from such profound environmental shifts. The relative constancy of the heritability of social status *despite* these changes is therefore quite devastating to the environmental determinist view. Perhaps environmental factors do more to alter the heritability of intelligence, social status, and/or other important traits/outcomes where material circumstances are much poorer than those that have been canvassed in the studies cited above. These environments must be quite rare, however, since late medieval England was extremely poor by modern standards. There is thus robust evidence that, certainly in the modern world, individual differences in important behavioral traits/outcomes are probably mostly a result of genetic rather than (nongenetic) environmental influences.

It is easy for critics of hereditarian science to posit that the heritability coefficients from standard behavior genetic studies *may* not track the causal effects of genetic variation on trait/outcome variation, *may* be contaminated with unmeasured environmental effects that mimic heritable variation, *may* be substantially variable across environments due to environmental effects on gene expression, and so on. Some of these possibilities are likely not favorable to

environmental determinists and are probably compatible with revised genetic determinism. For example, gene-environment correlations involving environmental effects that partially produce phenotypic variation may be largely generated by genetic effects on human behavior (e.g., genetic factors leading individuals to sort into certain environments). Moreover, it is far from obvious that attempts to disrupt apparently spontaneously emerging gene-environment correlations for the sake of engendering behavioral equality would be successful (indeed, it is well known that Soviet social engineering effectively along these lines was an utter failure with morally abhorrent consequences [MacDonald 2010]).

That notwithstanding, such objections from environmental determinists are unconvincing without supporting evidence. (And, in any event, environmental determinists who are unsatisfied with hereditarian explanations that offer anything less than fully elaborated causal pathways linking genetic variation to differential behavioral traits/outcomes would do well to recognize that proposed environmental explanations of phenotypic variability are, at best, no less often and no less seriously incomplete.) Take for example the previously noted claim that the high heritability of IQ may simply reflect the tendency of people who look alike to be treated alike. As it happens, this idea has not withstood empirical scrutiny, since the correlation between physical attractiveness and IQ is near zero (Lee 2010; as Lee notes, environmental determinists could respond with the claim that some other aspect of appearance may be causally relevant – but, again, without supportive evidence, this is mere hand waving; crucially, Segal, Hernandez, Graham and Ettinger's 2018 study of genetically unrelated "look-alikes" offers strong evidence that "[t]he criticism that [monozygotic] twins are alike in personality because their matched looks invite similar treatment by others" is false (p. 402)). This entry has already detailed the failure of efforts to find environmental effects that non-negligibly modify the heritability of IQ or social status, or to find any environmental intervention that can reliably and permanently raise IQ in

healthy individuals (see also Haier 2017). Indeed, attempts to find evidence for extravagant claims about the power of environmental effects to modify behavioral trait/outcome heritability have had minimal success at best (Duncan 2014). For example, despite early findings indicating that the heritability of IQ may vary dramatically as a function of socioeconomic status (e.g. Turkheimer et al. 2003), subsequent research on this effect has determined that it is, if real at all, of very small size (see, e.g., Woodley of Menie, Pallesen and Sarraf 2018). These results align with straightforward theoretical interpretations of high heritability coefficients, i.e., that differences in traits/outcomes with such coefficients are mostly genetically determined. Moreover, it should be recognized that environmental determinists exhibit a questionable selectivity with respect to the heritability estimates about which they are skeptical. Human height is consistently found to be highly heritable, yet no one, or at least very few people, seems motivated to argue that this finding is spurious and may be due, for example, to unmeasured environmental factors that mimic heritable variation. Only in the case of politically sensitive traits/outcomes, such as intelligence, do such objections seem to be offered with any significant frequency.

General critiques of twin studies and related behavior genetic research designs abound in the academic world (e.g., Joseph 2014; Richardson 2017); but all substantive elements of these critiques have been repeatedly addressed (Barnes et al. 2014; Felson 2014; Liu et al. 2018) and have not inspired doubt regarding the soundness of these methods among the relevant scientists – the results of twin studies are still recognized as basically accurate estimates of trait/outcome heritability and "environmentality" (see Polderman et al. 2015; see also Bouchard, Jr. 1987, 2009 on the "pseudoanalytical" nature of sweeping critiques of behavior genetics and hereditarianism). (For example, Liu et al. 2018 show that misestimation of twins' genetic and epigenetic relatedness tends to *downwardly* bias heritability estimates [but only to a small extent, and primarily for high- as opposed to low-heritability

phenotypes], whereas Richardson 2017 wrongly insinuates that the failure of quantitative genetic studies to accurately measure twin epigenetic relatedness generally *upwardly* biases heritability estimates.) Furthermore, the high heritability estimates found for a number of traits/outcomes via twin studies have been replicated using different study designs (for an example, see Schwabe, Janss and van den Berg 2017). Some argue that the “problem of missing heritability” in molecular genetic studies of complex quantitative behavioral traits – i.e. the likely causal genetic variants identified account for far less of the variation in these traits than expected in the light of traditional behavior genetic estimates – casts doubt on the validity of twin studies. However these findings are not surprising (given that molecular genetic approaches to estimating trait/outcome heritability are still in their infancy, and thus have serious limitations), and it is unlikely that phenomena that would create deep problems for standard behavior genetic estimates of trait/outcome heritability are at play, even if trait/outcome heritability is (currently) difficult to totally account for at the molecular genetic level of analysis (see Kendler et al. 2016; Kendler et al., as with Schwabe et al. 2017, offer highly compelling evidence that twin studies *do not* overestimate the heritability of traits, and thus that biases in twin studies likely *do not* contribute appreciably to the problem of missing heritability).

Though the facts thus far presented already leave the environmental determinist position very much in doubt, there are further considerations that render it clearly untenable. First, it must be recognized that environmental determinists expect or assert that environmental factors that are under human control are primarily responsible for behavioral trait/outcome variation. Intellectuals such as Kitcher (mentioned above), for example, hope that the facts about differential human behavioral traits/outcomes will be friendly to ordinary “aspirations” for, e.g., social mobility. It would hardly help their case if behavioral differences among humans were matters not of genetics but of some other biological and/or environmental factors that are outside of relevant

human control (Sesardic 2005, pp. 178–182 raises the same point), such as aspects of the uterine environment or “random developmental noise” (Jensen 1980). But as it happens, understanding of whatever truly environmental effects on trait/outcome variation that behavior genetic studies may detect is quite poor – by adulthood, these influences appear to be completely independent, or nearly so, of “shared” experiences of, e.g., families and schools (shared environmental effects increase the similarity of persons living in the same household, net of the effects of genetic relatedness). They are perhaps environmental experiences that are unique to individuals, which does not inspire confidence about possible efforts to control them such as to, say, raise individuals’ IQ. And to some extent, what registers in behavior genetic studies as “non-shared” environmental effects is measurement error, and perhaps poorly understood chance events and idiosyncratic and random developmental processes. Burt, Klahr and Klump (2015) note that non-shared environmental effects are generally not stable over time prior to adulthood, which is consistent with the impression that these apparent effects are mostly “noise”; the authors do note other research showing that the effects of non-shared environment become more temporally stable in adulthood, but even then, the research that they cite suggests that only a minority of such effects are stable among adults.

The inclusion of measurement error in estimates of non-shared environmental influence probably explains the tendency for higher-precision measurements of whatever phenotype is under investigation to produce larger heritability and smaller “non-shared environmentality” coefficients. A possible example of this effect is found in Rindermann’s (2007) analysis of international differences in academic and cognitive test performance, which found that a single psychometric factor – analogous to the highly heritable *g* at the individual-differences level – accounted for 94–95% of the variance. This suggests the possibility that the nongenetic variance in intelligence within groups (which is typically estimated at around 20% of the variance among adults)

is largely measurement error and other random factors that may be broadly the same across groups, such that genetic differences may account for almost all of the variance at higher levels of aggregation, where such evenly distributed “noise” is canceled out. The possibility that intelligence exhibits such minimal true “environmentality” is yet another piece of information that fits with the consistent failure to find any environmental variable the manipulation of which can reliably and permanently raise the IQ of healthy individuals (Protzko 2015; Woodley of Menie et al. 2018), which is to say that not only behavior genetic studies suggest the relative importance of (*controllable*) environmental factors in determining variability in adult human behavioral traits/outcomes.

Additionally, Riemann and Kandler (2010) found that personality traits exhibit very high heritabilities (some around 85-90% heritable) and low “non-shared environmentalities” when multiple methods of trait/outcome measurement are used, an approach expected to reduce measurement error. By contrast, studies of the heritability of personality traits that use less sophisticated measurement techniques typically find heritabilities of 50% or less. This again indicates that a substantial portion of non-shared environmental variation found in behavior genetic studies is due to measurement error.

Studies of life history speed in humans also suggest that “controllable” environmental factors widely thought to substantially affect human behavioral variation may in fact be highly unimportant. Sociologists have long maintained that discrimination and other forms of “socially constructed” (i.e., in principle changeable through nongenetic processes) disadvantage are central to explaining correlations among mental and physical health, relationship quality, sexual behavior, subjective well-being, personality, and other domains subsumed under life history speed. Specifically, sociologists believe that discrimination on the basis of and other disadvantages associated with differences of race, sex, and class explain a great deal of human behavioral variation. But it turns out that the latter sociological variables, even when all pooled together (and with

educational attainment added), explain *at best* less than 10% of the variance among life history traits, whereas the highly heritable Super-K factor explains nearly all (91%) of the variance (Figueredo et al. 2007). The failure of these variables, which are so central to mainstream sociological theory and analysis, to meaningfully explain the interrelations of such critical human traits/outcomes is remarkable.

Finally, it must be noted that to the extent that environment matters for important human behavioral traits/outcomes, some of the relevant environmental factors are likely genetic. There is a substantial literature on social epistasis, i.e., inter-organismal genomic transactions whereby the genotype of one organism affects the gene expression and phenotypic development of another organism (see Woodley of Menie et al. 2017b). Revised genetic determinism therefore extends in a surprising way to the environment as well.

Furthermore, though much has been made in some quarters about the power of environmental factors to epigenetically modify organisms, those offering such claims frequently miss the fact that epigenetic effects operate by way of preexisting genetic potentials and do not undo the significance of (likely) genetic variation captured in standard heritability coefficients (Figueredo et al. [in preparation](#)).

Critics of hereditarian science should recognize that attempts to trivialize the role of genes in determining individual differences easily fall into opposition to basic principles of modern evolutionary theory. Evolution via selection simply is differential reproductive success as a function of heritable phenotypic variation and environmental circumstances (with heritable factors subject to mutation). If traits cannot be reliably transmitted across generations, because they are open to such radical environmental/epigenetic alteration that genetic variation should not be expected to yield at least fairly reliable patterns of trait/outcome variation, then it would seem that the very idea of evolution by selection is in trouble. This implication suggests that the efforts of anti-hereditarians to attenuate or even sever the connection between inter-individual genetic and trait/outcome variation are without much sense.

Conclusion

Genetic determinism, though indefensible in its traditional but entirely fictitious form, is eminently defensible as revised and presented here, given the best pertinent scientific evidence to date. There are various possible moral, political, and existential reasons that individuals resist the latter thesis, but these of course do not count as reasons to reject it as false.

Homonegativity; Sexual prejudice

Definition

An umbrella term for a negative (attitudinal, affective, or behavioral) response towards homosexuality and homosexuals

Introduction

The impact of the genetic makeup on homophobia and its interplay with environmental factors have been neglected for a long time, because social factors were conceived as purely environmental

(e.g., parental socialization) and thought to be the key contributors to the development of attitudes, prejudices, and discriminatory behavior towards homosexuals. The shifts in the scientific paradigms and the subsequent (re-)emergence of biological and genetic hypotheses have led to studies demonstrating genetic influences.

Evidence for a genetic contribution to homophobia comes from behavior genetic studies. For example, a study on 4,688 Australian twins, who completed a questionnaire concerning sexual behavior and attitudes towards homosexuals, found 36 % of individual differences in homophobic attitudes to be attributable to genetic differences (Verweij et al. 2008). The remaining variance in attitudes toward homosexuality was primarily due to environmental factors not shared by twins reared together. Thus, the contribution of objectively shared environmental influences to individual differences in homophobia, such as norms and values taught by parents as socialized aspects in forming positive or negative attitudes toward homosexuals, was negligible.

The findings of substantial genetic influences on homophobia are primarily based on studies of twins and self-reports on attitudes toward homosexuality. However, classical twin study designs cannot take gene-environment interplay into account, and self-reports, in particular in case of social attitudes, may be biased to some degree by socially desirable responding, which itself may be heritable to some degree. Thus, we actually do not know whether estimates of genetic variance reflect substantial genetic influences, gene-environment interplay, or artifact. Despite these limitations, we can speculate on cogent explanations and scientifically sound hypotheses on the genetic basis of individual differences in homophobia.

Genetically Driven Threat Perception and Management

Past research showed that evolved neurophysiological threat management systems help navigate the individual through unfamiliar and, thus, potentially threatening situations by triggering

specific cognitive, affective, and behavioral responses to avoid threat to one's own physical, mental, and social integrity. Those fitness-relevant threats range from endangerment of the physical health through contagion and contamination, through aggression of conspecifics, to threat to one's own status in the social group (Boyer and Bergstrom 2011). Indeed, the association between negative attitudes towards strangers or unfamiliar behaviors and a diversity of expected (rational and irrational) threats has been repeatedly demonstrated (e.g., Riek et al. 2006).

Similarly, for heterosexual men, negative cognitive responses (i.e., prejudice; e.g., Kite and Whitley 1996), negative affective responses (i.e., disgust, anger, and fear; e.g., Inbar et al. 2009; Zeichner and Reidy 2009), and negative behavioral responses (i.e., aggression against homosexual men; e.g., Parrott and Zeichner 2008) towards (particularly male) homosexuals have been observed, suggesting homosexuality to be an unfamiliar, fitness-threatening stimulus. Consequently, the genetic basis of homophobic reactions may reflect phylogenetically developed autonomic threat-avoidance mechanisms. Moreover, genetic differences in the sensitivity to potential threat, manifested in individually differing thresholds for the categorization of unfamiliar stimuli, such as homosexuality, may result in genetic variance in homophobia (hypothesis 1).

However, these threat management mechanisms cannot explain profound genetic variance, because selection processes would act to decrease genetic variance in threat management systems due to the fact that individuals with the best (i.e., most sensitive) threat management systems would be the fittest in this regard. Considering that homosexuals do not pose a realistic threat to one's own fitness, threat management systems are equally sensitive and responsive to cues of threat that are subjective, imagined, or irrational. Hence, the functionality of threat management systems may also play a vital role. This functionality may depend on other heritable characteristics, such as intelligence or personality traits. For example, lower cognitive abilities predict greater anti-homosexual prejudice (e.g., Hodson and Busseri 2012). This association was partially

mediated by right-wing authoritarianism (RWA). RWA is a substantially heritable personality characteristic which has been discussed to be closely associated with avoidance of societal and cultural threat (e.g., Onraet et al. 2013), hinting at the importance of threat experience in the development of outgroup attitudes. This is positively correlated with homophobia (see ► [“Social Hypotheses of Homophobia”](#)). Thus, genetic variance in homophobia might also be due to genetic differences in the functionality of threat perception and processing (hypothesis 2).

Mutation-Selection Balance and Assortative Mating

Apart from genetic differences in threat perception and management, the genetic variance in homophobia might be influenced by occasional spontaneous gene mutations, which counteract selective processes. Especially since complex human traits and attitudes are thought to be polygenic (i.e., influenced by a number of genes), and the probability of spontaneous gene mutations is exponentially heightened for polygenic characteristics, the genetic variance of homophobia within a population may be due to a mutation-selection balance (hypothesis 3).

Another plausible explanation is positive assortative mating, which has been found for diverse attitudes and negativity toward others (e.g., Kandler et al. 2015). Positive assortative mating – that is, the choice of partner regarding characteristic similarity that is normally substantial for attitudes (e.g., shared prejudice towards homosexuality) – has two implications: It acts to increase genetic similarity among relatives and increases the polarization of genetic differences in polygenic phenotypes in a population. Taking positive assortative mating of the twins' parents into account, Verweij and colleagues (2008) estimated a total of 51 % of variance in homophobia to be due to genetic factors. Consequently, assortative mating reflects a possible mechanism that acts to maintain genetic variance in homophobia (hypothesis 4).

Sex Differences in Homophobia

Negative cognitive, affective, and behavioral responses towards homosexuals have been found to be less likely for women (e.g., Kite and Whitley 1996). This indicates that homosexuals and homosexuality might constitute a threatening stimulus exclusively for male heterosexuals. Several accounts might explain this sex difference.

Masculinity has been linked to homophobia (see ► [“Social Hypotheses of Homophobia”](#)), which may be amplified under threat (—ened masculinity). From a phylogenetic point of view, displaying masculinity might not only be advantageous for the reproductive fitness of a male but also for the fitness of all ingroup members insofar as the permanent expression of one’s or the group’s strength and physical superiority over others and outgroup members might avoid intergroup threat. Whereas heterosexual men might not see homosexual men as rivals within the group, they may have a genetically driven tendency to perceive homosexual male group members as too weak and too feminine to defend the ingroup against threat due to intergroup rivalry (hypothesis 5).

In addition, it has been shown that women are more socially oriented and seek more contact and intimacy with others, which is in accordance with their respective ancestral roles (e.g., care for the offspring and elder group members as opposed to exploration and joint defense of the territory). This might allude to the fact that familial socialization might be more important for individual differences in homophobic responses in women. In line with this differentiation, Verweij and colleagues (2008) reported that 55 % of the variance in homophobic attitudes in men was due to genetic differences, whereas genetic factors could account for only 20 % of individual differences in homophobic tendencies in women. Consequently, genetic factors may play a larger role in individual differences in homophobia for men (hypothesis 6).

develop differently depending upon their genetic sensitivity to environmental influences. Humans are self-determined individuals who make their own choices and environments based upon their heritable characteristics. The genetic control of the construction of experiences and the exposure to certain environments can act as propulsive mechanism of reinforcing initial tendencies. For example, (primarily male) heterosexual homophobes tend to avoid confrontation with homosexuals if possible, which – in terms of the contact hypothesis (see below) – reduces the probability of change in homophobic tendencies (Hodson and Busseri 2012). To the contrary, this genetically driven avoidance of environments is an example of a so-called active gene-environment correlation which reinforces homophobic tendencies (hypothesis 7).

While the aforementioned hypotheses can explain recurring and persistent homophobia in a society and underlying genetic variance in individual homophobic tendencies, they cannot explain the average decline in prejudice towards homosexuals in Western societies (e.g., Herek 2015). Changes in the individual’s environment, whether actively initiated (e.g., leaving a former, more conservative and joining a new, more open-minded neighborhood and community due to relocation) or by chance (e.g., having homosexual colleagues or neighbors), can alter the perception of threat and attitudes towards homosexuals. Similarly, positive contact with homosexuals can diminish homophobia (see ► [“Social Hypotheses of Homophobia”](#)). Such environmental factors might be enforced through societal developments and changes, which establish an atmosphere of “de-stigmatization,” acceptance, and inclusion of sexual minorities like homosexuals. In contrast, the societal exclusion of homosexuals (e.g., in Russia or Saudi Arabia) may enhance the genetic diathesis. In other words, the genetic influence on homophobia may depend on the sociocultural context (hypothesis 8).

Gene-Environment Interplay

Environments provide the range and variety of developmental opportunities in which people

Conclusion

In sum, several theories and findings suggest a substantial contribution of genetic factors and

gene-environment interplay to homophobia. In order to confirm these hypotheses, large-scale genetically informative studies are required, such as longitudinal extended-twin-family studies with measured environments, ideally separately for men and women. Furthermore, future research should use comprehensive measures of homophobic attitudes and behavior beyond self-reports (e.g., implicit measures or reports from well-informed peers) to disentangle substance from measurement artifact. Finally, neurogenomic research can provide important insights into the molecular genetic basis and neuronal mediators of cognitive (i.e., prejudice), affective (e.g., disgust), and behavioral components (i.e., discrimination) of homophobia.

Adolescence; Pubescence; Sexual maturity

Definition

Puberty is defined as the physical transition from sexual immaturity to being sexually mature.

Introduction

Adolescence is sometimes considered a synonymous term but implies more of a psychosocial

maturation that comes with puberty. The mean age for the onset of first signs of puberty among girls is around 10.5 years of age (range: 8–12 years), while among boys, it is around 11.5 years (range: 9–13 years) (Susman et al. 2010). Some variability occurs between individuals with regard to the timing and sequence of pubertal maturation. However, most of boys and girls follow a predictable course through pubertal maturation.

Pubertal onset in both girls and boys appear to be occurring earlier all over the world as compared to that reported in the literature previously (Sørensen et al. 2010). Several factors like increased BMI and fat mass have been implicated in causing this earlier pubertal onset, but substantial evidence is still lacking in this regard. Also, pubertal timing varies significantly between different ethnic groups. Genetics seem to play an important role in causing these racial/ethnic differences (Gajdos et al. 2010).

Gonadotropin-releasing hormone (GnRH) is the master hormone of the reproductive endocrine system, largely controlling the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from pituitary gonadotrope cells. An increase in the pulsatile secretion of GnRH from the hypothalamus is considered to be a critical hormonal event in puberty. FSH and LH then evoke steroidogenesis and gametogenesis from the gonads, culminating in secondary sexual features development and fertility. There are multiple other factors involved in the initiation of puberty as well, and the complex interactions between genetic and environmental factors controlling

this process are just beginning to be understood (Fig. 1).

Regulation of Puberty

Puberty is a mysterious phenomenon and not all is known to answer the various complicated steps occurring in this process. Several mechanisms have been implicated in the onset of puberty. The process seems to undergo neuropeptide, genetic, metabolic, and environmental regulation.

Neuropeptide Regulation of Puberty

A sustained increase in pulsatile release of gonadotrophin-releasing hormone (GnRH) from the hypothalamus is an essential, final event that defines the initiation of puberty. This depends on coordinated changes in transsynaptic and glial–neuronal communication, consisting of activating neuronal and glial excitatory inputs to the GnRH neuronal network and the loss of transsynaptic inhibitory tone.

The prevalent excitatory systems stimulating GnRH secretion involve a neuronal component and a glial component. The neuronal component consists of excitatory amino acids such as glutamate and peptides such as kisspeptin and neurokinin B. The glial component uses growth factors such as TGF- β , EGF, IGF-1, and bFGF and small molecules for cell–cell signaling such as SynCAM1 and RPTP β .

KiSS1 located on chromosome 1q32.1 encodes the peptide kisspeptin, which acts via its receptor, encoded by the gene KISS1R (also known as GPR54) located on 19p13.3. It is

thought that KISS1 signaling through KISS1R in the hypothalamus at the end of the juvenile phase of development may contribute to the pubertal resurgence of pulsatile GnRH release. The three key features of the kisspeptin–Gpr54–GnRH neuron axis leading up to puberty are (i) the expression of adult-like levels of Gpr54 mRNA in GnRH neurons well in advance of puberty, (ii) a modest increase in the electrical response of GnRH neurons to Gpr54 activation across post-natal development, and (iii) the “sudden” appearance of kisspeptin fibers surrounding GnRH neuron cell bodies/proximal dendrites just prior to puberty onset. Another important pathway in the initiation of puberty may be TAC3 signaling. TAC3 is located on chromosome 12q13.3, and the gene that encodes its receptor TACR3 on chromosome 4q24, and loss of function mutation in these genes have been associated with hypogonadotropic hypogonadism (Topaloglu et al. 2009).

GABAergic and opiateergic neurons provide transsynaptic inhibitory control to the system, but GABA neurons also exert direct excitatory effects on GnRH neurons. New evidence suggests that additional peptides inhibit GnRH neuronal activity. The discovery of such gonadotropin-inhibitory hormones, examples of which include the RF amide peptides, RFRP1 and RFRP3 (encoded by the QFRP gene on chromosome 9q34.12), have further clarified the role of genes that inhibit the GnRH axis until the appropriate signals to initiate puberty come in to play (Jiang et al. 2003).

Other pathways, especially in the appetite control center of the hypothalamus, have also been shown to influence pubertal onset. Neuropeptide Y (NPY) and Agouti-related Peptide (AgRP) are orexigenic peptides that have been found to influence the production of proopiomelanocortin (POMC), another neuropeptide which affects normal pubertal onset (Martos-Moreno et al. 2010).

Genetic Factors Regulating Puberty

Genetic factors have been established to account for 50–75% of the variability in timing of normal pubertal onset. Several genetic loci have been identified which are associated with age of

pubertal onset. The genetic mechanisms that provide encompassing coordination to this cellular network are not clearly known. The timing of puberty varies greatly among healthy individuals in the general population and is influenced by both genetic and environmental factors (Gajdos et al. 2010). The high correlation of the onset of puberty seen within racial/ethnic groups, within families, and between monozygotic compared to dizygotic twins all provides evidence for genetic regulation of pubertal timing. These data suggest that 50–80% of the variation in pubertal timing is determined by genetic factors. Environmental and physiologic effects also influence the timing of puberty, and there is evidence supporting secular trends in the timing of puberty. It is possible that gene by environment interactions play an important role in regulating the timing of puberty.

It is tempting to consider that a single gene may be responsible for the initiation of puberty, since mutations in genes such as GNRHR, GPR54, TAC3, TACR3, and KISS1 result in pubertal failure. Functional studies have failed to demonstrate that any one of these single genes plays a commanding role in synchronizing the neuronal and glial networks involved in the initiation of puberty. This has led to the current concept of genetic networks regulating the neuroendocrine control of puberty initiation (Ojeda et al. 2010). This network is envisioned to be a host of functionally related genes hierarchically arranged. The highest level of control in this network is likely provided by transcriptional regulators that, by directing expression of key subordinate genes, impose an integrative level of coordination to the neuronal and glial subsets involved in initiating the pubertal process.

The use of new techniques of genetic analysis coupled to systems biology strategies should provide not only the experimental bases supporting this concept but also unveil the existence of crucial components of network control not yet identified. The question of whether the first step in the initiation of puberty is a loss of central restraint or the activation of stimulatory inputs to GNRH neurons still remains unanswered. It may very well be that transcriptional repression and activation of key genes occurs simultaneously to

orchestrate this complex process. One recent advance in this direction is the identification of the polymorphisms with age at menarche in the leptin and leptin receptor genes in humans (Riestra et al. 2011). In addition, we are learning more about various transcription factors such as thyroid transcription factor 1 (TTF1) and a transcription factor encoded by the gene C14ORF4 located on chromosome 14q24.3 which modulate gonadotropin-releasing hormone (GnRH) expression (Cukier et al. 2013) (Figs. 2 and 3, Table 1).

Metabolic Control of Puberty

Both growth and reproduction consume high levels of energy, requiring suitable energy stores to face these physiological functions. The state of body energy reserves is a key determinant for the onset of puberty. During the last two decades, our knowledge concerning how peptides produced in the digestive tract (in charge of energy intake) and in adipose tissue (in charge of energy storage) provide information regarding metabolic status to the CNS has increased dramatically. Moreover,

these peptides have been shown to play an important role in modulating the gonadotropic axis with their absence or an imbalance in their secretion being able to disturb pubertal onset or progression (Martos-Moreno et al. 2010).

Leptin is an adipocyte-derived hormone and its synthesis is directly related to the amount of body fat. Thus it is involved in the control of energy homeostasis and modulates several neuroendocrine systems, including the HPG axis. Animal knockout models have shown that infertility is characteristic of leptin-deficient mice (ob/ob) and that this can be overcome by leptin treatment. Humans that are leptin deficient due to homozygous gene mutations present with hypogonadotropic hypogonadism, with long-term recombinant leptin treatment being able to achieve pulsatile nocturnal gonadotropin secretion in these patients. Humans with leptin receptor deficiency present with different degrees of hypogonadotropic hypogonadism.

Leptin is considered to be the main peripheral signal providing information about the body's energy stores to the hypothalamic circuits in

Genetic Influences of Puberty, Fig. 2 Different genes involved in disorders of delayed puberty. *HH* hypogonadotropic hypogonadism, *CDGP* constitutional delay of growth and development. (Gajdos et al. 2010)

Genetic Influences of Puberty,

Fig. 3 Transcriptional regulation of the initiation of puberty. (Ojeda et al. 2010)

charge of controlling energy homeostasis, thus communicating this information to the HPG axis by means of mechanisms that are far from being fully understood. Leptin appears to play a permissive role in the initiation of puberty and in the maintenance of the reproductive function. The earlier initiation of puberty seen in obese children may also be partly explained by higher leptin levels. The role of other adipokines such as adiponectin and resistin on the HPG axis is currently poorly understood.

Growing evidence suggests that insulin and leptin interact to downregulate arcuate nucleus (ARC) production of orexigenic peptides such as NPY and AgRP and, in collaboration with serotonin, enhance POMC production and release. Thus insulin could be another peripheral metabolic signal involved in HPG axis functioning.

Ghrelin is a gut-derived hormone, whose function as a growth hormone secretagogue is well described. More recently, it has been shown that

ghrelin modulates energy homeostasis by stimulating the expression of the genes encoding NPY and AgRP in the arcuate nucleus of the hypothalamus and by binding to presynaptic terminals of arcuate NPY and POMC neurons, respectively stimulating and inhibiting their activity and peptide release. This results in a net orexigenic effect, functionally opposite to that produced by leptin. Thus it is currently thought that ghrelin plays a role in reporting information regarding the fuel availability in the body to the CNS, and that there is an inverse relationship between activation of the HPG axis and ghrelin levels. The role of other gut-derived factors such as peptide YY (PYY) is currently being explored.

Environmental Influences on Puberty

Since genetic background explains 50–80% of variability in the timing of puberty, it is not surprising that the observed environmental effects are rather modest when individual exposures are

assessed. The fact that the age of onset of puberty has been declining in the USA since the mid-1990s, with similar trends are being seen more recently in Europe, points towards such rapid changes having environmental rather than genetic causes (Toppari and Juul 2010).

Endocrine disrupting chemicals have thus been implicated as being such environmental factors affecting pubertal onset. Endocrine disrupters can cause pubertal disorders by several mechanisms. They can act as hormone agonists or antagonists or both depending on the dose and background hormone levels, i.e., the same compound can be an agonist when the level of endogenous hormone is very low (childhood), whereas it can be an antagonist when the real hormone is available (adulthood). Multiple chemical exposures have been considered, but definitive studies are lacking. Examples of such chemicals include polychlorinated and polybrominated biphenyls (PCBs and PBBs), phthalates, dioxins, DDT, and

lead. Apart from the association of lead and delayed puberty, the evidence is unclear.

Conclusion

It is now clear that initiation of puberty involves complex neurohormonal stimuli that are regulated by various genetic and environmental factors. Advances in genetic technologies and a systems biology approach will help with diagnosis and treatment of disorders of pubertal development and help us understand environmental influences that perturb the balance of pubertal development.

Genetic Load

Michael A. Woodley of Menie

Center Leo Apostel for Interdisciplinary Studies,
Vrije Universiteit Brussel, Brussels, Belgium
Unz Foundation, Palo Alto, CA, USA

Definition

Genetic load describes the fitness burden resulting (principally) from deleterious mutations that accumulate within an organism's genome and is estimated relative to a hypothetical mutation-free or fitness-optimized genome. Individual differences in mutation load, especially with respect to pleiotropic mutations, may be a major source of individual differences in both the variance and covariance among fitness indicating traits in humans and other sexually reproducing taxa.

Introduction

This entry will first review the conceptual basics of genetic load and will present a mathematical overview of the phenomenon. It will then consider the phenomenon in relation to its applicability to evolutionary psychology.

Review

Genetic Load

Genetic load is a term coined by Muller (1950) to describe a phenomenon first noted by Haldane (1937), namely the fitness loss that accrues principally from the accumulation of deleterious mutations (this being *mutation load*) in addition to the effects of *segregation/migration load* (the fitness costs associated with breaking up coadapted allelic complexes) and *substitutional load* (the fitness costs associated with limits on trait evolvability imposed the low probability of desirable alleles being found in combination with one another), estimated relative to a hypothetical mutation-free or fitness-optimized genome.

In sexually reproducing organisms, mutations (the principal contributor to genetic load) can arise spontaneously, i.e., where the mutation occurs in the germ cells of a parent and is then passed on to the diploid genome of the offspring or where the mutation gets passed on to the offspring from the parents as a *legacy mutation*. Mutations are more likely to contribute to mutation load via accumulation under conditions of relaxed purifying selection, i.e., when the fitness cost of the mutations are mitigated by changes in selection pressures, or in instances where the mutations have only very mild effects on fitness, such as where they are harbored by recessive alleles. Mutation load also increases rapidly in instances where populations become more inbred and homozygous, typically in response to decreased population size. Where purifying selection is insufficient to remove mutations at a rate proportional to the rate at which they drift to fixation, *mutational meltdown* occurs, whereby the population collapses rapidly under the fitness burden of runaway mutation accumulation.

The equations used in estimating genetic load (L) in their most basic form consider single locus systems comprised of alleles $A_1 \dots A_n$, which have a fitness distribution of $w_1 \dots w_n$ and frequencies $p_1 \dots p_n$, thus L can be calculated as follows:

$$L = \frac{w_{\max} - \bar{w}}{w_{\max}} \quad (1)$$

Here, $w_{\max}$ corresponds to the hypothetical (i.e., load-free) fitness for the given distribution of fitnesses and $\bar{w}$ corresponds to the mean of the fitnesses weighted by the frequencies of their given alleles. If $w_{\max} = 1$ then Eq. 1 simplifies to:

$$L = 1 - \bar{w} \quad (2)$$

This equation necessarily makes certain simplifying assumptions, such as the assumption that the population is at equilibrium (i.e., no frequency dependent selection on the alleles). The assumption of a fitness optimized, load-free genome is also problematic in as much as estimates of mutation load and the fitness costs of subsequent

mutation accumulation have led to a *mutation load paradox* when applied to human reproduction, where based on the addition of around 100 de novo mutations to the average diploid genome every generation, very high fitness loss should be observed (i.e., 88 % of individuals should fail to reproduce and reproducing females should engage in very high compensatory reproduction in order to maintain population viability) (Kondrashov and Crow 1993). The paradox stems specifically from the observation that reproductive failure and compensatory reproduction on this scale is simply not observed in modern, industrialized populations. Solutions to the mutation load paradox have emphasized the role of relative fitness differentials between individuals of differing mutation loads as a source of soft purifying selection in modern populations (Lesecque et al. 2012). It has also been observed that very high reproductive failure and compensatory reproduction was characteristic of historical Western populations and is still characteristic of compensatory hunter-gatherer populations (Volk and Atkinson 2008), hence the hypothetical mutation-free genome may actually have been closer to the reproductive optimum historically and that modern industrialized populations by comparison might therefore be in the process of undergoing gradual mutational meltdown by virtue of relaxed purifying selection and mutation accumulation (e.g., Lynch 2016).

The Significance of the Concept to Evolutionary Psychology

A critical application of the concept of genetic and mutation load in particular to evolutionary psychology has been in the development of *fitness indicators theory* (Houle 2000; Miller 2000), which provides an evolutionary framework within which the adaptive function of human individual differences can be understood.

Fitness indicators theory is premised on the assumption that among sexually reproducing organisms such as humans, deleterious germ-line mutations can influence fitness outcomes in ways related to their pleiotropic effects on traits, meaning that they can influence the development of multiple traits simultaneously. This has led to the

prediction that there exists a latent *fitness factor* (typically abbreviated to *F*) among traits believed to signal the sensitivity of development to perturbation stemming from the presence of deleterious mutations (Houle 2000; Miller 2000). Thus in sexually reproducing taxa, there should exist genetic correlations among seemingly quite distinct traits, encompassing aspects of physical condition, behavior, health, and reproductive viability, high-levels of which are *unconditionally favored* by *sexual selection* across different environments (Penke et al. 2007).

Under conditions where purifying selection occurs in proportion to the fitness costs of spontaneously occurring germ-line mutations, individual differences in and genetic correlations among fitness salient traits will be maintained within a population, as spontaneously arising deleterious mutations conferring few fitness disadvantages to their carriers (by virtue of recessiveness) can persist as part of genetic load for many generations, with the addition of each new mutation cumulatively reducing the fitness of the lineage relative to others that are burdened with fewer such mutations. This mechanism by which variance is maintained with respect to fitness salient traits in a population is known as *mutation-selection balance* (Fisher 1930) and is the principal mechanism through which population variance in *F* is believed to be maintained (Penke et al. 2007).

Conclusion

Genetic load is an old concept in population and evolutionary genetics. It is a concept with clear utility to evolutionary psychology also, especially as it pertains to reconciling the massive modularity approach, with its emphasis on human universal and domain-specific cognitive adaptations, with the existence of both apparent individual differences in and also covariance among the functioning of not only these mechanisms but also other physiological sources of individual differences pertaining to physical condition (Miller 2000). The relevance of the genetic load concept to the issue of future micro-evolutionary trends in fitness stemming from relaxed purifying selection

and mutation accumulation in industrialized populations is also significant.

Genetic Polygamy

Jon Sefcek
Kent State University at Ashtabula,
Ashtabula, OH, USA

Definition

Genetic Polygamy refers to patterns of inheritance that indicate different male and female effective population sizes through genetic analysis. It is different than “social polygamy,” in that it is a measure of the actual genetic parentage that allows researchers to trace paternity, rather than the apparent or culturally institutionalized mating patterns that are witnessed.

Introduction

Evidence of polygamous mating patterns is generally identified by the apparent pair-bonding behaviors of individuals within a group. In humans this may be displayed through the institutionalized mating practices within cultures. However, these apparent behavioral patterns are only a proximate measure of a species, or groups, actual mating pattern. Other ways to determine such patterns are by examining the dimorphic physical or behavioral traits that males and females display. Sex differences in traits such as body size, ornamentation, and behavior give some evidence of a species evolutionary mating history, where larger dimorphisms relate to larger disparities in male and female effective population sizes (i.e., polygamous mating). The differences in the amount of variation between male and female genetic markers offer another line of evidence. This question may be explored in a variety of ways, with the two most common being examining the ratio of variation in the X-chromosome versus autosomal DNA and the amount of distinct genetic lineages in the nonrecombining portions of DNA (e.g., mitochondrial and the non-recombining portion of the Y-chromosome).

Basic Methods for Examining Genetic Variation

The first approach is to compare the amount of neutral genetic variation on the X-chromosome (X) to that of the autosomes. Because the X-chromosome is only passed through matrilineal descent and the autosomes are passed by both matrilineal and patrilineal inheritance, the expectation is that in a monogamous species with an approximately 1:1 sex ratio at reproduction, we should see ratio of diversity of 0.75 between X and the autosomes (Hammer et al. 2008). This ratio is due to a 25 % reduction of X due to males only carrying one copy. In species that are polygamous we should see deviations from this ratio.

The second method focuses on measuring the amount of genetic variation in the mitochondrial DNA (mtDNA) and nonrecombining portion of the Y-chromosome (NRY). These genetic markers are uniparentally inherited, with MtDNA passed down the matrilineal line and NRY passed down the patrilineal line. Here, researchers group together alleles into haplogroups (historically referred to as clades). These haplogroups (named alphabetically A, B, C, etc.) are combinations of alleles that are genetically linked and therefore passed down from parent to offspring in an unbroken line of descent. Over evolutionary time, mutations cause slight changes in the structure of these genetic markers, leading to a nested (or hierarchical) structure where an individual belongs to a haplogroup at the top of the structure down through a haplotype and subclade. By counting the number of mutations (in relation to a standard mutational clock, which varies by location on the particular allele) researchers can identify the approximate date when a particular haplogroup coalesced.

Human Genetic Patterns of Mating

Whether referring to X-chromosome versus autosome, mtDNA, or NRY variation, the genetic diversity between matrilineal and patrilineal lines would be an indication of the amount of reproductive variance in a population (i.e., the

number of males relative to females that reproduced). In species that have an approximately 1:1 sex ratio at reproductive age, different genetic patterns would be expected based on their evolutionary mating patterns. With a monogamous pattern, where there is low reproductive variance, we would expect a similar number of mtDNA and NRY haplogroups and approximately a 0.75 ratio of X to autosomal DNA variation (Hammer et al. 2008). In a polygynous system, with high reproductive variance, we would expect to see more variance in the number of mtDNA versus NRY lineages, as well as more variation in X. In polyandrous species, where one female is maintaining exclusive mating privileges with multiple males, we would expect more NRY lineages and less X variation, because only a few females would be reproducing. This last expectation, however, may be attenuated where there are patterns of *kin-based* polyandry (i.e., a single female mating with related males).

To date, genetic evidence aimed at identifying the species-typical mating pattern in humans has been difficult to interpret, with single-study evidence of lower, equal, and higher effective population sizes in males. For example, a study by Segurel et al. (2008) found differences in variation between X and autosomes in a direction indicating a larger effective population size for females (i.e., polygyny) in Central Asian populations. Whereas a study by Ramachandran et al. (2004) showed no differences in effective population size (i.e., monogamy) in a population of genetic markers extending across Africa, America, Asia, Europe, the Middle East, and Oceania. However, much of this discrepancy may be due to methodological difference between studies (i.e., sample size, number of genetic markers uses, genetic assay techniques). A recent review by Heyer et al. (2012) has summarized these findings by comparing the methodological strengths and limitations of each study. Their conclusion was that across the majority of studies genetic evidence has identified higher levels of X variation than expected in monogamous systems.

Studies examining mtDNA and NRY haplogroups have offered a similar answer. To date, the number of mtDNA versus NRY

haplogroups is higher, suggesting a history of a smaller effective population size in males. Research by Lippold et al. (2014) came to a similar conclusion. By examining the X and NRY genetic markers in males from 51 different populations, Lippold et al. identified a pattern of X versus NRY variation suggesting polygyny and potentially sex-specific migration over human history. As a further indication, researchers have compared the coalescence dates of particular haplotypes to known historical events. One noteworthy example comes from NRY haplotype C-M217. This genetic marker is spread throughout 16 distinct cultural populations in Central Asia, is shared by approximately 8 % of Asian men, and shows a coalescence date in Mongolia approximately one-thousand years ago (Zerjal et al. 2003). Due to these factors and that it exists in known descendants of Genghis Khan, researchers have suggested that this genetic marker belongs to Ghengis Khan himself, the Borjigin Clan from which he came, or one of his descendants.

Conclusion

An evolutionary history of sex-biased processes in human mating is evident through a variety of methods ranging from comparison of phenotypic traits to genetic markers. While current social mating trends may be toward more apparently monogamous social bonds (more accurately, serially monogamous), the amount of genetic variation between X and autosomes, and X and NRY at both regional (e.g., Segural et al. 2008) and global (e.g., Lippold et al. 2014) levels suggests an evolutionary history of higher effective population sizes for females versus males. Taken as a whole, we may conclude that humans have been *at least* mildly polygynous over evolutionary history.

Epigenetic	Changes in gene activity that is influenced by factors other than DNA sequence alterations, such as environmental exposures
Genetic diversity	The total number of characteristics in the genetic makeup of a species
Genetic variation	The tendency of genetic characteristics to vary within and among populations
Genotype (v)	The process of determining which genetic variants an individual possesses
Heritability	A statistical determination of how much variation of a trait is attributable to genetics
Missing heritability	The observation that the total known genetic variations attributed to a trait cannot account for all of the trait’s estimated heritability
Monogenic inheritance	When a single gene determines a genetic trait
Penetrance	The proportion of individuals carrying a variant (allele) of a gene that also express the trait associated with that variant
Phenotype	An observable physical or biochemical trait
Polygenic inheritance	When two or more genes determine a genetic trait

Allele A variant form of a gene which may or may not result in a different observable trait

Introduction

Genetic diversity ensures species’ survival though enabling evolutionary adaptations in response to environmental changes. The genetic variation which allows for this diversity is mostly due to de novo mutations which create new gene variants (alleles), random mating, and the shuffling between maternally and paternally inherited chromosomes during meiosis (homologous recombination). While most genetic variations are neutral, meaning they do not alter any observable trait, some do affect gene function and may lead to improved or decreased fitness. The forces of natural selection over time increase the frequency of advantageous alleles while selecting against those

that put the carrier at a reproductive disadvantage. Thus, particularly devastating genetic diseases are rare, and more common disease-associated genetic variants tend to occur late in life after reproduction, such as cancer and dementia. While there exist many traits and diseases that are caused by a single gene alone (monogenic), most are polygenic in nature, meaning that two or more genes contribute to the phenotype. Often a large number of genes are involved, each with a small effect and may interact with each other and/or the environment. Examples of polygenic traits are height, weight, and skin pigmentation. Therefore, in isolation, most functional genetic alterations predispose rather than predetermine. Genetic predisposition is the increased likelihood of developing a particular trait or disease as influenced by one's own genetic makeup. While many polygenic traits seem to have an obvious genetic component, it is difficult to associate any specific genetic variant as it is unusual that a single gene's effect would be sufficient. This is especially true for behavioral traits and psychological disorders where the environment plays an undoubtable role as well. Even so, there are ways to determine whether a trait or disease has a high genetic component without knowing the underlying genetic causes.

Estimating the Heritability of a Trait

For complex traits such as depression, intelligence, or susceptibility to various diseases, it's wise to first establish an estimate of how much of the phenotypic variance is due to inheritance before attempting to implicate any genetic variants. One classic means of determining the heritability of a trait is through twin studies which measure the similarity of a trait between monozygotic twins as compared to dizygotic twins. Monozygotic twins are derived from a single fertilized egg and thus share the same genetic material, while dizygotic twins, formed from separate eggs, share about half of their genes. Because both sets of twins share the same environment, at least in childhood, this approach controls for much of the environmental contribution. If monozygotic twins

resemble each other more than dizygotic twins for a particular trait, then the heritability of that trait is estimated as twice the observed difference. For example, monozygotic twins generally have a correlation of about 40% for depression (meaning that if one experiences depression, the other twin will also in about 40% of cases), while dizygotic twins have a correlation of 20%. The difference in the correlation between both sets of twins (40–20) doubled is 40%. Therefore, the genetic contribution (heritability) to depression is estimated at ~40%. Twin studies have suggested high heritability for anxiety, intelligence, and numerous behavioral traits (Boomsma et al. 2002).

Implicating Genetic Variants

When a trait or disease is suspected to be inherited, there are various approaches that can be employed to identify the genes and variants responsible. One approach is through linkage analysis, a hypothesis-neutral means to find segments of DNA which all affected persons of a family share but the healthy relatives do not have. This is possible because genetic variants that are close in proximity tend to be inherited together. The analysis begins with genotyping genetic "markers" (highly variable regions of the DNA) on each chromosome for both affected and unaffected individuals of a family. Once a region is identified as shared between and unique to those affected, additional markers are added to further narrow the search within this region until a specific gene and genetic mutation is implicated. This method is most appropriate when attempting to map monogenic disease mutations and is responsible for discovering the gene for cystic fibrosis (Bowcock et al. 1986).

For complex traits and disease predisposition, a better approach to implicating genetic variants is through association, such as a *genome-wide association study* (GWAS). As the name implies, these studies look for genomic variants that are statistically more prevalent in cases versus controls by genotyping across the entire genomes of hundreds or thousands of individuals both with and without

the trait/disease of interest. GWA studies have identified predisposition variants in traits such as anxiety (Otowa et al. 2016), longevity (Zeng et al. 2016), and even intelligence (Davies et al. 2011). However, they lack the statistical power necessary to detect rare variants (which are more likely to have a high effect) and instead tend to implicate common variants with low effect. Even so, these low-effect variants are informative as they may highlight biological mechanisms underlying a disease. For example, an interesting relationship has been established between susceptibility to schizophrenia and certain variants located in genes responsible for the major histocompatibility complex, a key component in immunity. However, the biology underlying schizophrenia and the immune system is not entirely clear (Sekar et al. 2016). Similarly, GWA studies often identify disease-associated variants in areas of the genome with no known function. Because there exist various reasons that a spurious association could occur, replicating findings through additional association studies is encouraged, and associated variants should be functionally validated through experimentation in cellular or animal models.

Population Genetics and Environmental Influences

Population genetics is a subfield focused on genetic variation within and among different human populations. Specifically, population geneticists study phenomena such as adaptation, speciation, and migration through examining the fluctuation of allele frequencies with time across various populations, making it an indispensable tool for understanding evolutionary biology. Allele frequency refers to the incidence of a particular variant in a population at a given time in history. The frequency of an allele is not stable as it is subject to four main evolutionary forces: natural selection, new mutations, gene flow (the transfer of alleles between populations), and genetic drift (variation due to chance). Selection for or against a particular allele can be inferred through the age of the mutation and its frequency in the population. For example, if a mutation has

occurred recently but is observed at a high frequency in a population, this is evidence for positive selection. Estimating the age of genetic variants is possible since DNA is shuffled during meiosis and therefore is inherited in segments called “haploblocks.” A haploblock refers to a stretch of DNA that related individuals share due to recent ancestry. With each generation, additional chromosomal shuffling occurs, resulting in haploblock decay, meaning the shared stretch of DNA between ancestors lessens with each generation. Therefore, one can estimate the age of a genetic variant by examining the haploblock size of as many individuals as possible with this same variant, to see how much of their surrounding DNA sequence is also shared. A longer haploblock signifies a young variant as chromosomal shuffling had not had enough time to break up that shared surrounding segment. Vice versa, an allele on a very small haploblock indicates that the allele is a lot older as many generations and meiosis has likely occurred.

Environmental factors exert a heavy influence on selection, and therefore whether a mutation is advantageous or not often depends to the environment of the carrier. Relatively recently, it was discovered that the environment can lead to phenotypic variation via “epigenetic” alterations. Epigenetics refers to changes in gene activity not caused by any alteration in the DNA sequence. Instead, the change in activity is often due to chromosome structural alterations which inhibit or promote gene accessibility thus inhibiting or promoting the ability for cellular machinery to transcribe and translate the gene’s message into its respective protein product. These chromosomal changes are influenced by one’s environment. For example, various studies have confirmed a correlation between fetal malnutrition due during pregnancy and predisposition to obesity in adulthood. This phenomenon is hypothesized to be due to a “*thrifty phenotype*,” whereby epigenetic alterations to metabolic pathways occur to prepare the fetus for survival in famine. If there is no famine, then the metabolism of the child is maladapted to the actual environment and may be prone to metabolic diseases and obesity (Rourke 2015). There is still a lot unknown about

epigenetic mechanisms, but they are believed to have the ability to be passed on to the next generation.

Genetic Testing

In terms of health care, genetic testing was once mostly limited to confirming a suspected diagnosis. However, due to the ever-decreasing cost of genome sequencing, testing is now being offered to assess an individual's risk of developing disease in the future and even to predict response to certain therapeutic drugs. The field of oncology has really been a pioneer for genetic testing in this aspect. Much research has gone into discovering mutations that lead to an increased lifetime risk of developing certain cancers, especially those known to have a relatively high heritable component. For example, current estimates suggest that approximately 25% of ovarian cancer cases arise due to an inherited risk mutation (Walsh et al. 2011). Therefore, individuals with a suspicious family history are encouraged to seek genetic testing as risk reducing surgeries and therapies are available to those who have inherited a predisposing mutation. However, as with many multifactorial diseases, there is a gap in our knowledge of the genetics underlying the predisposition. Often, the known genetic variations attributed to a disease do not account for its total estimated heritability. This is referred to as *the missing heritability issue*. A recent study focused on ovarian cancer risk has suggested that a portion of the missing heritability is likely due to genes that have not yet been implicated in predisposition and rare mutations in established disease genes whose effect on protein function is not yet described and that high risk may be incurred through the inheritance of multiple low-risk variants (Stafford et al. 2017). For certain diseases, this unexplained heritability often limits how informative genetic testing can be. However, even when the total genetic cause of a disease is known, there may be no preventative measures to avoid disease onset and no treatment.

Conclusion

The field of genetics has experienced vast growth since completing the sequencing of the human genome in 2003. This monumental achievement is responsible for many scientific advancements in health care; however the genetics of disease predisposition have proven to be highly complex and often dependent other genetic and nongenetic factors. Sex differences, environmental stimuli, genetic penetrance, and epigenetics all play a crucial role in predisposition, and each trait or disease is unique in these aspects. As technologies advance, so does our understanding of genetics and therefore our ability to apply this knowledge where applicable.

Synonyms

Coefficient of relatedness; Coefficient of relationship; Relatedness coefficient; Relatedness parameter

Definition

The probability that an allele in one individual is also found in another individual.

Introduction

Relatedness is an important parameter in kin selection or more generally inclusive fitness theory. One significant puzzle in the history of evolutionary theorizing is the evolution of altruism. Kin selection, with the use of the relatedness parameter, often denoted by r , permits to solve this puzzle.

The Puzzle of Altruism

A classical approach to natural selection tells us that only traits which confer a heritable fitness (reproductive) advantage to their bearer will evolve by natural selection. For instance, suppose a population of organisms which vary in height and in which the taller an organism is the higher its reproductive output. We could imagine that the organisms are giraffes and that giraffes which are taller have access to leaves on the top of trees while smaller giraffes do not. Because of this access to more resources, taller giraffes can produce more offspring than smaller ones. If taller giraffes produce taller offspring, everything else being equal, so that height is heritable, then tallness will evolve by natural selection. Under this picture of evolution by natural selection, following the three conditions of variation, difference in fitness, and heritability (Lewontin 1970), only traits that are beneficial to the individual bearer of these traits can evolve by natural selection.

Following this Darwinian scheme, we should thus expect to see only traits that confer a fitness advantage to their bearer in nature, since every time a mutation conferring a disadvantage emerges in the population it should be eliminated by natural selection (assuming what is known as genetic drift can be ignored). Thus, in our example, we should not expect giraffes to get smaller over time on average, because small giraffes have a lower probability to reproduce than tall giraffes. Although this Darwinian scheme seems impeccable, it is contradicted by empirical evidence: everywhere one looks, one finds traits costly to the individual. Think about the ultimate sacrifice of a worker in an ant colony. The worker defends

the colony, takes care of the offspring produced by the queen, or gathers food, and yet it never has the chance to reproduce; only the queen does. Ants and termites, for which the reproductive activity of the colony is typically carried by a single female, have been estimated to represent only 2% of the total number of species of insects. Yet, their biomass is estimated to represent more than a quarter of the total animal biomass (Wilson 1990). Eusocial insects are evolutionary very successful despite contradicting the classical scheme for Darwinian evolution.

Solving the Puzzle

As described by Dawkins (1976), one solution to the problem of altruism proposed by some biologists has been to say that, although a costly trait does not provide any advantage to the individual that bears it, it nevertheless provides an advantage to its group or species. In fact, if workers suddenly stopped defending the hive, taking care of the larvae, or bringing food, the colony would soon disappear. But this explanation faces the problem that any worker unwilling to pay the reproductive cost paid by other workers would get an evolutionary advantage over individuals paying the cost. In fact, following this logic, a worker deciding to reproduce instead of paying the cost of gathering food, taking care of the larvae or defending the nest, would soon produce workers like it with the same properties, all of which would have a (short term) evolutionary advantage over sterile workers. Thus, the “good of the group” proposal cannot be the whole story, for, following its rationale, groups would irremediably be subverted by selfish individuals.

William Hamilton (1936–2000) was the first one to give a formal solution to the problem of altruism without relying on a form of the good of the group argument (Hamilton 1963, 1964a, b). His solution is reductionist in that it requires taking the perspective of a gene borne by an individual, also known as the “gene’s eye view,” which was made famous by George Williams’s *Natural Selection and Adaptation* (1966) and even more so by Richard Dawkins’ *The Selfish Gene* (1976).

Before Hamilton, some evolutionists, including J. S. B. Haldane and Darwin himself, seem to have gestured to the same solution to the puzzle of altruism, but not as rigorously as Hamilton did.

Hamilton’s solution to the problem of altruism is that an allele incurring a fitness cost to its bearer can be compensated for if another individual with the same allele receives a benefit from the first individual which is equal or superior to the cost that it incurred. For instance, suppose an individual “actor” with an allele **A** helps another individual “recipient” with the same allele by providing the recipient with some resources. In doing so the actor pays a cost in terms of offspring it can produce. It is altruistic. We could imagine that without helping the recipient, the actor would produce three offspring while if it helps the recipient it can only produce two offspring. We could further suppose that the recipient, without any help from the actor, would be unable to produce any offspring, but produce two offspring when it receives some help. In this setting, if we compare the number of **A** alleles present in the offspring population when the actor helps the recipient to the situation in which it does not, the outcome will be four offspring (each with a single copy of the **A** allele) rather than three, respectively. Even though the actor produces fewer offspring when it helps the recipient, it is evolutionarily advantageous from the point of view of allele **A** that the actor helps the recipient. Helping the recipient will, after all, permit an increase in the number of copies of **A** when compared to the situation in which no help is provided. More formally, because the benefit obtained by the recipient “*b*” is higher than the cost “*c*” incurred by the actor – so that $b - c > 0$ – the altruistic behavior, if it is heritable, can evolve (i.e., successfully “invade” the population).

Although this reasoning provides a solution to the problem of altruism, there is a complication. We assumed in the example that the recipient has allele **A** with certainty. Yet, from the point of view of the actor, there is typically no guarantee that the recipient has allele **A**. Suppose that the actor helps the recipient, yet the recipient does not have allele **A**. In such a case, being altruistic is evolutionary disadvantageous since the *guaranteed* number of

copies of **A** in the offspring generation is, then, two rather than three.

The coefficient of relatedness r measures the probability from the point of view of the actor with a given allele (say **A**) that the recipient also has this allele. The more technical definition of r is slightly different since it takes into account the average probability of sharing an allele in the population, but this need not concern us here (for details see Bourke 2011, p. 31). The reason r stands for “relatedness” is that one common cause of having a copy of the same allele is being related by descent, as in actors and recipients belonging to the same family. But the modern understanding of r is more general than that as we will see below.

Using r in Hamilton’s Rule

For a population in which social interaction is dictated by family structure, it can be evolutionarily advantageous to be an altruist. Whether it is evolutionarily advantageous from the point of a view of an allele not only depends on the cost of the actor and benefit of the recipient, as we saw earlier, but also on the probability that the recipient receiving the benefit bears the same allele as the actor which is measured by r . Modifying the rule for the evolution of altruism given earlier ($b - c > 0$) by considering relatedness, we obtain $rb - c > 0$, which is known as “Hamilton’s rule.”

If we take our going example and assume that the actor and the recipient are full siblings, then because the benefit obtained by the recipient is two offspring and the relatedness is 0.5, it is not more advantageous, from the point of view of allele **A**, for the actor to help the recipient. In fact, in both cases, on average, the number of copies of **A** at the offspring generation will be 3. We have $rb - c = 0$ since $0.5 \times 2 - 1 = 0$. In a different situation in which the cost of one offspring paid by the actor would lead to a benefit of three offspring for the recipient (a full sibling), the altruistic behavior could evolve. In fact, we have $rb - c > 0$ since $0.5 \times 3 - 1 = 0.5$. With the actor and the recipient being first cousins, altruism is however disadvantageous. In fact, assuming the previous cost of one

offspring for the actor but a benefit of three offspring for the recipient, because r is now 0.125 instead of 0.5, we have $rb - c < 0$ ($0.125 \times 3 - 1 = -0.625$).

Although a classical context in which relatedness plays a role is family, this is not the only one. It has been imagined that individuals with the same allele could recognize one another even without being related. This is known as the “green-beard effect” (Dawkins 1976; Gardner and West 2010). Even though empirically, “greenbeards” seem to be limited to a small number of cases and mostly not relevant for human evolution (Gardner and West 2010), their possibility shows that relatedness, following its most general definition, does not solely measure the extent to which individuals socially interacting are related by descent. It is much more general than that. Note also that it does not require recognition between individuals. Individuals might be altruistic towards one another because they live in the same place rather than because they know they are siblings. All these subtleties mean that despite the simplicity of Hamilton’s rule, relatedness is a concept one should manipulate with care.

Conclusion

Relatedness is an important concept in evolutionary theory. Embedded within inclusive fitness theory, it extends a solution to one of the most important puzzles in evolutionary theory, namely, the evolution of altruism. Together with reciprocal altruism proposed by Trivers (1971), inclusive fitness theory is one of several evolutionary mechanisms for explaining the formidable level of cooperation in humans.

Genetic Relatedness Affects Aid to Kin

Sigal Tifferet

Synonyms

[Inclusive fitness](#); [Kin selection](#)

Definition

Any two same-sex humans share about 99.9 % of their genes. Family members also share significant portions of the remaining 0.1 %. This shared portion is referred to as genetic relatedness. In

reference to a target individual, siblings or parents have a genetic relatedness of $r = 0.50$; nephews, nieces, aunts, or uncles $r = 0.25$; and cousins $r = 0.125$. The level of genetic relatedness is assumed to affect the amount of aid reciprocated by two individuals, everything else being equal.

Introduction

Why do we help our relatives? One could claim that a gene that promotes helping kin should not have been selected for, since it involves a price to the helper. For many years this dilemma was indeed a problem in evolutionary theory. The breakthrough arrived when Hamilton (1964) suggested that in some instances a helper can gain an evolutionary advantage by assisting his or her relatives. Hamilton's (1964) Kin-selection theory claims that an individual can gain inclusive fitness through the promotion of reproduction of genetically related kin. According to Hamilton (1964, p. 17), "a gene may receive positive selection even though disadvantageous to its bearers if it causes them to confer sufficiently large advantages on relatives". Specifically, Hamilton posited that altruistic acts can be selected for when $b \cdot r > c$, where b is the benefit to the recipient, r is the level of genetic relatedness between the altruist and the recipient, and c is the cost to the altruist. Hamilton's law does not necessitate assisting kin in all animals and under all conditions. It simply indicates the conditions under which kin assistance can be selected for (Park 2007).

Animal Studies

Following Hamilton's law a debate arose as to whether it could empirically explain animal behavior. Do helpers actually prefer their close kin over their distant ones? Some of the studies showed that individuals provide greater help to closer kin, but others did not (Griffin and West 2003). Using meta-analytic tools Griffin and West (2003) summed up the results from 18 cooperatively breeding vertebrate species and found that,

overall, relatedness correlated with helping behavior ($r = .33$). Next, they attempted to explain the variability in the results and demonstrated that in species where the help was less beneficial to the target, effect sizes were smaller. This is congruent with Hamilton's law that claimed that altruism is constrained by the benefit that it provides.

Self-Report Measures

What about humans? Do we follow Hamilton's law? In an early series of studies, Japanese and American students were asked to choose one of two people to assist (Burnstein et al. 1994). The assistance was needed for a life-or-death condition (saving from a burning house) or for everyday assistance (running an errand). In each choice the recipients differed in their genetic relatedness to the student: acquaintance or acquaintance's child ($r = 0$); cousin ($r = 0.125$); nephew, niece, aunt, or uncle ($r = 0.25$); and sibling or parent ($r = 0.50$). Each of the choices included additional variables such as the age, health, gender, or wealth of the recipient. In all studies there was a consistently large effect for relatedness, with assistance increasing with relatedness. This was true for both life-or-death instances and for everyday help. Later studies confirmed the link between genetic relatedness and the reported willingness to assist a person in need (e.g., Korchmaros and Kenny 2006). Similar results were also obtained when participants were asked about their past behaviors. For example, in a large-scale Dutch survey, participants were asked to report how much concern they gave or received from a specific sibling (Pollet 2007). The results showed that half-siblings reported less concern for each other in comparison to full siblings. This difference held true for maternal half-siblings as well, although they grew up together.

Observational Measures

Are these results limited to self-report or are there observational data establishing that humans assist

their close kin more than their distant kin? This question has been evaluated in Western society in two major life events: marriage and death. In Israel it is customary for newlyweds to record the monetary gifts they receive from each wedding guest. An analysis of such records revealed that kin offered more money than non-kin, and highly related kin ($r = 0.50$ and 0.25) offered more money than more distant kin ($r = 0.125$ and 0.625). However, no significant differences were found between the two highly related kin groups nor between the two distant kin groups (Tifferet et al. 2012). At the end of life, an analysis of British Columbian wills found that the genetic relatedness with the beneficiaries predicted the generosity of the benefactor (Webster et al. 2008). The mean estate percentage granted to relatives of $r = 0.125$, 0.25 , and 0.50 were 1.9 %, 9.7 %, and 38.7 %, respectively. This demonstrated that close kin were granted more than distant kin. Observations of traditional societies also show that relatedness is associated with helping. Among the Ache of Paraguay, for example, nuclear families share food with others. Observations showed that close kin ($r = 0.50$) were more likely to receive food than were distant kin ($r = 0.125$ – 0.25), but there did not seem to be a difference between distant kin and unrelated families (Gurven et al. 2000). The results, however, were difficult to interpret since relatedness was highly correlated with geographical proximity, so it is not clear whether the increased food share resulted from proximity or relatedness.

Proximate Mechanisms

It appears that in general, individuals help their close kin more than they do their distant ones. What would drive them to do so? Korchmaros and Kenny (2006) identified a number of mechanisms. First, genetic relatedness arouses a feeling of obligation that drives a person to help. Second, it arouses emotional closeness that also drives a person to help. This emotional closeness is further enhanced due to past cohabitation, perceived similarity, and frequent interactions, all hallmarks of genetic relatedness. Note that past cohabitation,

perceived similarity, and frequent interactions may serve as cues by which we recognize our kin and identify their level of relatedness. As such, they could be the basis of evolved mechanisms for kin preference.

Conclusion

Preferential altruism toward close kin has been documented in humans and other animal species. These acts are congruent with Hamilton's (1964) law, claiming that altruism may be selected for when targeted toward kin. The link between actual genetic relatedness and altruism may be mediated by proximate cues of genetic relatedness. More studies are required that assess actual behaviors in natural settings.

Genetic Relatedness and Child Abuse

Brittany Lorentz

University of South Carolina – Beaufort,
Bluffton, SC, USA

Synonyms

Childhood maltreatment; Emotional; Neglect; Physical

Definition

Physical or emotional abuse or neglect to an individual 18 years of age or younger by a parent or parent substitute.

Introduction

Child abuse can be represented in a number of ways: physical abuse, physical neglect, emotional abuse, emotional neglect, or threats of maltreatment. According to the National Incidence Study (1996) by Sedlak and Broadhurst, physical abuse is anyone 18 years and younger who experienced injury or is/was at the risk of injury by a parent or parent substitute. This involves being hit with a hand or object or being kicked, shaken, thrown, burned, stabbed, or choked. Physical neglect is the harm or endangerment as an effect of inadequate nutrition, clothing, hygiene, and/or supervision. In addition, child abuse can also be emotional abuse, the use of nonphysical punishment or threats of maltreatment or emotional neglect, absence of affection and/or emotional support, or the exposure to domestic abuse.

Kin Selection

Child abuse can occur at any age up to 18 years and by either a biological parent or parent substitute. Based on an evolutionary perspective, parental love and care is established on the fitness value that the child shares (Temrin et al. 2011). Stepparents attempt to feel the kindness of that of a biological parent but often do not result in the lack of connectedness and satisfying relationships with children. Thus, parent substitutes (stepparents) are going to show less attentiveness based on lack of genetic relatedness and has been proven to explicate higher data for child abuse and homicide found within stepfamilies. Additionally, natural selection has focused on the intensity of parental care in our ancestry, and therefore these favored genotypes and phenotypes that triumph in parenting to develop individuals successful for reproduction have become the ones to flourish (Daly and Wilson 1986). With this, Daley and Wilson (n.d.), predicated that step relationships have a higher rate than genetic-related parent relationships with the controlling factor of socioeconomic status for child maltreatment and now referred to as the “Cinderella effect.” Based on the

stepfather effect on child abuse, results from Hilton et al. (2015) study on genetic relatedness found that among 144 men having at least one stepchild, 18% assaulted their stepchild, and among 361 men with at least one genetically related child, 8% assaulted their related child. Among ten households consisting of both genetic-related and stepchildren, only the stepchildren were abused within nine of the homes and one stepchild and one genetic-related child were both abused, and there were no scenarios where a genetic-related child was abused and a stepchild was spared (Daly and Wilson n.d.). Within households the paternal involvement in a child’s life is evident in the influence of abuse; paternal involvement in child caregiving is a leading protective mechanism (Lee et al. 2009). Conclusively, Hilton et al. (2015) propose that among men with both genetic-related children and stepchildren, the odds of assaulting a stepchild is twice as likely of assaulting a genetic-related child.

On the other hand, although studies have shown that stepparents abuse and sometimes kill their children at a higher rate than genetic-related parents, this does not implicate stepparents being the main factor but rather an underlying correlation with parental characteristics (Daly and Wilson n.d.).

Parental Characteristics

In addition to genetic relatedness, it has been found that fathers with pre-existing dysfunction characteristics are more probable to enter stepparent roles and have an increased risk of presenting childhood maltreatment. These abusers often have previous convictions; have personality traits of anxiety, depression, irritability, and antisociality; or have entered parenthood at a young age and face economic hardship. However, according to Temrin et al. (2011), “even if there are other differences between stepfamilies and families with two genetic parents than the non-genetic relatedness between stepparents and stepchild, these differences cannot

explain the Cinderella-effect, since the violence in families that include both stepchildren and genetic children is discriminatively targeted towards the stepchildren.” Hilton et al. (2015) found that step-parents with antisocial personality assaulted their stepchildren by 6% more than related children supporting their hypothesis of discriminative parental solicitude. Although Hilton et al. (2015) discovered that antisociality within men is correlated with a greater risk to assault stepchildren and, in some cases, display more assaultive behaviors, this personality trait cannot entirely be accounted for in the stepfather effect in child abuse. Moreover, the history of convictions and criminal behaviors lies within families of stepparents more so than families with two genetic parents and can be a confounding factor in the explanation of child homicide and abuse in stepfamilies. Temrin et al. (2011) concluded that there is a higher rate of crime-prone individuals within stepfamilies, and offenders of child homicide are significantly higher within parents of previous crimes.

Another confounding characteristic to have a significant impact on the outcomes of child abuse is socioeconomic status. Socioeconomic status puts stress on one’s family, and this stress of poverty can highly influence the likelihood of parents to abuse and/or kill their children. Correspondingly, the stress of poverty is a high factor in divorce and remarriage, therefore leading to stepparent relationships a related correlate of abuse (Daly and Wilson n.d.). Within well-established stepfamilies that are of middle class, it was reported that 53% of stepfathers and 25% of stepmothers were able to say that they had parental feelings for their stepchildren (Daly and Wilson n.d.) leading back to the evolutionary prospective of fitness value and therefore stepparents spending less time and attention to stepchildren (emotional neglect). Having a positive involvement within a child’s life is noticeably associated with a lower level of risk for childhood maltreatment and physical abuse (Lee et al. 2009). These indications of characteristics on stepparents increase the risk for child abuse and maltreatment.

Conclusion

All in all, children from stepfamilies are at a significantly higher risk for child abuse and maltreatment than children of families with two genetic parents based on a Darwinian natural selection and family characteristics. This conclusion has been scientifically proven through the process known as the kin selection theory or the “Cinderella effect” (Temrin et al. 2011). Families with both genetic parents are significantly more likely to have households consisting of love and attentiveness, less criminal activity, higher socioeconomic status, and therefore less child abuse and maltreatment.

Genital Evolution

Rebecca L. Burch
State University of New York at Oswego,
Oswego, NY, USA

Synonyms

[Penile evolution](#); [Co-evolution of the sexes](#);
[Sexual selection](#)

Definition

The shift in the morphology and other features of genitalia over the evolution of a given species.

Introduction

Among sexually reproducing species, the penis evolved to serve as an internal fertilization device. But across different species, penises come in a bewildering array of shapes and sizes (see Eberhard 1985). Penile morphology varies greatly across the animal kingdom. Length, girth, and major morphology differ greatly, but penises also differ in specific features: some have spines, barbs, spicules, huge coronal ridges, or none at all. For example, just in terms of length, penises range from 10 ft long (the blue whale) and 6 ft long (the elephant) to less than 1/100th of an inch (e.g., the mosquito). Many ungulates have a pronounced glans (zebra, horse, rhinoceros), and many primates have a tapered shaft (bonobo, short-tailed macaque). Other primate species, such as langurs, have a pronounced coronal ridge. Among the great apes, humans have the longest penis, average length 5.1 in., followed by chimpanzees at 3.1 in. Orangutans and gorillas have much shorter penises at 1.6 in. and 1.2 in., respectively.

Male and Female Genitalia

The vaginas of females of a given species also contain analogs or complements to penile morphology (long twisted oviducts, enforced walls, etc.) This is not to assume that female genitalia reflects male genitalia, but just the opposite. As female genitalia shifted to optimize female control over fertilizations, male genitalia evolved to match.

The human penis does not possess spicules or barbs, like many feline species, but it does have distinctive characteristics. In humans, the distinctive characteristics of the penis, relative to other primates, are its length, circumference, glans, and

coronal ridge. The typical erect human penis ranges from 127 to 178 mm in length (Masters and Johnson 1966), with an average circumference of 24.5 mm (Wessells et al. 1996). In contrast with our closest living relative, the human penis is roughly twice as long and wide as that of the common chimpanzee (Short 1981). The glans and coronal ridge of the human penis are also uniquely configured (Izor et al. 1981). The posterior portion of the human glans is larger in diameter than the penis shaft. At the junction between the shaft of the penis and the head is a protrusion which encircles the base of the glans called the coronal ridge. At the interface between the glans and the shaft, the coronal ridge is positioned perpendicular to the shaft. Common chimpanzees have no clearly differentiated glans or coronal ridge.

It has been suggested that species differences in genital morphology can be used as an indicator of sexual competition/selection (Dixson 1987; Eberhard 1996). Another example of genital difference that has obvious implications for reproduction and competition is testes size. Among the great apes, chimpanzees greatly outnumber the other species with 600 million sperm per ejaculate and 120 g testicles. Humans are a distant second with 250 million sperm per ejaculate and testicles that range from 25 to 50 g. Orangutans and gorillas possess considerably lower sperm counts (70 million and 50 million) and smaller testicles (35 and 30 g, respectively). Testes size and sperm counts directly reflect levels of sperm competition in these species: The larger the testes, the higher the sperm count, the greater the advantage in a highly competitive mating context. Chimpanzees have the highest levels of sperm competition, while gorillas have the lowest.

Sperm competition and mating competition do not only affect testicle size; they also affect other facets of mating and genitalia. Likewise, intrasexual competition is not the only factor in mating; intersexual competition also plays a large role. This can be seen above, with penile morphology shifting to match vaginal morphology. In humans, ovulation is not accompanied by salient external signals and fertilization occurs internally. As a consequence, females have a considerable

reproductive advantage over males. Whereas maternity is always certain, males have to contend with uncertain paternity, i.e., the possibility of their partners producing offspring sired by other males. Because of internal fertilization, human males have been selected to utilize paternal assurance tactics. First, male can increase the probability that the children he is caring for are carrying his genetic material by monitoring and/or sequestering the female partner during the period that she is fertile to minimize being cuckolded.

Secondly, should the female succeed in an extra-pair copulation (or at the very least be out of the man's sight for a period of time), the male can physiologically increase the probability of paternity through sperm competition. For example, Baker and Bellis (1989) have shown that sperm counts fluctuate according to how much time the male spends with his female partner. The less often the male sees his female partner over a 3-day period, the higher his sperm count upon resuming sexual intercourse with her. In the event of a double mating (having intercourse with more than one man within 5 days, according to Baker and Bellis), the man who increases his sperm count would have a greater chance of impregnating the female.

As evidence that the length of the human penis has been shaped by the recurrent adaptive problem of sperm competition, consider the following. During ejaculation, thrusting diminishes and vaginal penetration reaches its maximum point (Masters and Johnson 1966). Not only does this serve to release semen in close proximity to the cervical opening, but data on ejaculatory pressure shows that the first several ejaculatory contractions project seminal fluid with such force that it can be expelled at a distance of 30–60 cm if not contained in a vagina (Masters and Johnson 1966). Thus, there appear to have been a series of adaptations that serve to confine or focus the release of semen to the uppermost portion of the vaginal tract as a means of making it less vulnerable to displacement.

There has been some speculation that the human penis evolved not only as an internal fertilization device but also as a mechanism for displacing semen left by rival males in the female

reproductive tract (e.g., Baker and Bellis 1995). The human penis, with a larger glans and pronounced coronal ridge, could function to displace seminal fluid from other males in the vagina by forcing it back over/under the glans. The effect of repeated thrusting, according to this analysis, would be to draw/displace semen left by other males back away from the cervix. If a female copulated with more than one male within a short period of time, this would allow males to “scoop out” semen deposited by others before ejaculating (Baker and Bellis 1995). The coronal ridge acts to scoop semen left by other males away from the cervix and enables the male to replace rival semen with his own.

In support of this interpretation, Gallup et al. (2003) simulated sexual encounters using artificial models and found that phalluses approximating the human penis did displace artificial semen. In a series of studies designed to simulate sexual intercourse under laboratory conditions using artificial genitals, Gallup et al. found that when latex vaginas were loaded with simulated semen, phalluses that approximated the configuration of the human penis displaced 80 % or more of the semen by drawing it away from the cervical end of the vagina (Gallup et al. 2003). Through a series of experimental manipulations, it was determined that the coronal ridge may be an important feature of the penis in mediating semen displacement. Thus, as a mechanical means of affecting sperm competition, the human penis may enable successive males to displace foreign semen from the female reproductive tract and substitute their semen for those of their rivals. The displacement of artificial semen was robust across different prosthetic phalluses, different artificial vaginas, different semen recipes, and different semen viscosities.

In a survey of over 600 college students, reported in the same paper, Gallup et al. (2003) found that following periods of separation or allegations of female infidelity, both males and females report that penile thrusting is noticeably deeper and more vigorous. Therefore, how men unwittingly use their penis also may be related to its semen displacement properties, and the parameters of penile thrusting appear to vary as a

function of the likelihood that there may be semen from other males in the female reproductive tract.

Under conditions that raise the possibility of females engaging in extra-pair copulations (e.g., periods of separation, allegations of female infidelity by a regular male partner), Gallup et al. (2003) also found that males appear to modify the use of their penis in ways that are consistent with the displacement hypothesis.

Conclusion

There is ample evidence to support the hypothesis that genitalia have evolved not only for reproduction but to be successful at reproductive competition, both intrasexual and intersexual. In addition, data suggest that human genitalia was selected for both size and shape in order to ensure conception and paternity, and human behavior has also been selected to shift in ways to assist these strategies.

Definition

The effects of intrasexual competition and cryptic female choice on the evolution of genitalia.

Introduction

The genitalia of internally fertilizing animals are one of the most diverse characteristics within and across taxonomic groups. In many organisms, male genitalia exhibit extravagant spines, papilla, domes, hooks, and flaps and spines. The latter are generally made of keratin and can be found in a diverse array of animals including snakes and waterfowl; in domestic cats, penile spines scrape the female reproductive tract during copulation, which stimulates oviposition or egg-laying. Females too exhibit huge variation in genitalia; in the spotted hyena *Crocuta crocuta* females display a pseudo-penis that closely resembles a male penis, but is formed by the clitoris and fused

labia. In many organisms, particularly insects, male genitalia have other uses aside from reproduction, such as rubbing, grasping and stroking the female organs and sensory structures such as hairs and sensillae.

Extreme variation in genitalia is observed even amid some of the most similar looking species, making it one of the reliable traits to decipher between closely related animals. Both male and female genitalia exhibit extremely rapid evolution, and this is particularly evident in species that exhibit more promiscuous mating patterns. Genitalia evolve faster than practically any other morphological trait, and the explanation for this has been the subject of debate for decades (Langerhans et al. 2016). Researchers still argue that the evolution of genitalia remains relatively poorly understood.

Numerous theories have been proposed as to what forms of selection produce such distinct patterns in genital evolution. The three most popular theories are: (1) lock-and-key hypothesis, (2) pleiotropy hypothesis, and (3) sexual selection hypothesis, although these are not mutually exclusive.

Lock and Key

Originally proposed in 1844 by Léon Dufour (Dufour 1844), the lock-and-key theory is deeply ingrained among many biologists as a functional explanation for divergent genital evolution (Arnqvist 1997). The lock-and-key hypothesis suggests that male genitalia evolve in order to mechanically fit to their own species' female genitalia. Therefore, male genitalia evolve to be unique in order to be species-specific. Hence, the male genitalia are the “key” that mechanically corresponds perfectly with the “lock,” female genitalia.

Under this hypothesis, genitalia evolve to be highly specialised, in order to reduce the likelihood of hybridization with other species. Hybrids provide little evolutionary benefit, as generally most hybrids are not viable and will not form, and if hybrids do form, they are usually infertile. Thus, selection favors a pre-mating mechanical incompatibility between different species, in order to prevent mating occurring between them. Under

the lock and key hypothesis, any changes in male genitalia should be closely followed by changes in female genitalia resulting in male female coevolution (Simmons 2014). It has been suggested that selection driven by the lock-and-key mechanism should be stronger in monandrous species where females rarely re-mate, compared to polyandrous species where females mate with multiple males (Arnqvist 1997). It is expected that monandry would drive selection for reproductive isolation more intensely as the cost of mating with an individual of a different species is higher when re-mating is rare.

There are some criticisms of the lock-and-key hypothesis. It predicts that genital morphology between males and females should be complementary and it has been argued that female genitalia should be capable of physically excluding the male genitalia of other closely related species. However, studies have shown that female morphology is often uniform across species, without this ability to mechanically exclude similar species. Additionally, under this hypothesis alone some argue that genitalia are limited to stabilizing selection, which favors intermediate variants rather than extreme and diverse phenotypes, leading to relatively low amounts of phenotypic variation in genital morphology. As genitals are highly diverse, this does not conform to a fundamental assumption of the hypothesis (Eberhard 1985).

Pleiotropy

Mayr (1963) suggested that the vast differences observed in genitalia have a minor role, if any, in pre-mating mechanical isolation. Instead, Mayr suggested that pleiotropic effects acting on genes that code for both general morphological characters and genital traits were responsible for the strong variation we observe among genitalia. Evolutionary speaking, the morphological features that selection is working on are linked to genital characters, meaning any change in the selected features also affects the linked traits, almost as a side effect. Genitalia that have evolved through this hypothesis are proposed to exhibit high genetic and phenotypic variation and variation in genital morphology under the pleiotropy

hypothesis is assumed to be great but also largely nonfunctional (Arnqvist 1997). This results in no or very few instances of assortative meeting, in which males and females of similar phenotypes mate with one another more frequently. Under this assumption, preferential mating between male and female organisms for distantly different genital forms is not expected.

The pleiotropy hypothesis has come into question as it is unclear why genital organs should be disproportionately targeted by pleiotropy compared to other morphological traits (Hosken and Stockley 2004). Furthermore, male genitalia continuously exhibit high amounts of species-specificity, to such extent that it is a key trait to distinguish between closely related species as noted above (Langerhans et al. 2016). As under pleiotropism, selection is neutral but variation is high, species-specificity would not be a direct target of selection. This would make genital specificity difficult. Eberhard (1985) rejected the pleiotropy hypothesis based on observations that in many species in which males possess secondary sexual structures, also involved during copulation, it is these structures that exhibit the greatest amount of diversity in comparison to the primary genitalia.

Sexual Selection

Eberhard (1985) suggested that sexual selection could be responsible for the rapid diversification and evolution of genitalia. Sexual selection is driven by a preference for behavioral and morphological characteristics in the opposite sex, and competition within the same sex for access to members of the opposite sex (reviewed in Andersson 1994). Usually females choose between males, and males compete among themselves, as reproduction is generally more costly for females. As genitalia are well understood to be involved in sexual reproduction, to many, the idea that sexual selection is responsible for the evolution of genitalia seems indisputable (Arnqvist 1997).

The evidence for sexual selection driving genital diversity is based on observations of male genitalia increasing male fertilization success (reviewed in Simmons 2001). Sperm competition, postcopulatory male-male competition, occurs

when sperm from two or more males compete to fertilize the female's eggs within her reproductive tract. Sperm competition has been shown to operate in a number of ways, and one way is that males increase their fertilization success by removing sperm from rival males. For example, the genitalia of male damselflies *Calopteryx maculate* are spoon shaped and are used to scrape rival male sperm from the female reproductive tract. Variation in male genital morphology has also been observed to influence paternity success in the millipede *Antichiropus variabilis* while in the earwig *Euborellia brunneri* a longer and more exaggerated male genitalia results in greater sperm competitiveness. Therefore, sperm competition may be the leading force acting on genitals.

In addition to sperm competition, there are three other sexual selection-related mechanisms that have been suggested to explain rapid genital evolution; sexy sons (Runaway or Fisherian selection), good genes, and sexual conflict (Simmons 2001). The "sexy sons" hypothesis is associated with the inherited mate-attracting potential of the sons of a female. The "good genes" hypothesis is similar, but the benefits also include increased offspring viability (Hosken and Stockley 2004). Under both the "sexy sons" and the "good genes" hypotheses, the evolution of genital diversity is proposed to be driven by female choice for male genitals that best stimulate them when mating (Hosken and Stockley 2004). For example, in 2013, Yoshitaka Kamimura showed that in earwigs (*Euborellia brunneri*) longer genitalia is proposed to result from cryptic female choice for elongated genitalia, which in turn results in the production of larger sons; the mechanisms underlying this effect is not currently known.

Sexual conflict is the evolutionary arms race taking place between males and females in order for them to maximize their respective reproductive interests (Hosken and Stockley 2004). Essentially, unless reproductive interests are completely aligned, which they rarely are, sexual conflict favors traits that increase the fitness of one sex but comes at a cost to the other. For example, male ducks will often attempt to force copulation on females; however, the complex genitalia of female ducks make it mechanically difficult for sperm

from such matings to fertilize her eggs, as shown by Patricia Brennan's 2010 research. Male bed bugs (Heteroptera; Cimicidae) fertilize females by piercing her abdominal wall with the penis and injecting the sperm into her body cavity. This results in visible scars and leaves the female vulnerable to infection (Carayon 1966). Arguably, this traumatic insemination reduces female re-mating with competing males, and increases their investment in the current offspring if they perceive damage as a threat to survival. Females have evolved a counter adaption in the form of a specialized organ known as the spermalege; this tough fibrous organ is where the males pierce the female, and it reduces the physical and immunological costs imposed by this form of copulation. Thus, the coevolutionary arms race between males and females can potentially drive genital evolution.

Conclusion

Ongoing research currently favors sexual selection as the most likely mechanism responsible for the rapid diversification of genitalia, although it is less clear which mechanism of sexual selection is likely to be more important. However, the lock-and-key mechanism has not been disregarded as a possible mechanism in the evolution of genitalia. Sexual selection alone may not fully explain the specificity of genitalia that we observe between similar organisms. The lock-and-key mechanism may enforce species isolation, whereas sexual selection keeps genitalia evolving at a fast pace.

The focus of the majority of prior studies was previously centered on the divergence of genitalia in males, which resulted in the long-standing dominance of male-genitalia research. It was proposed that male genitalia appeared more elaborate and varied implying a greater diversity than the less-observable female genitalia (Arnqvist 1997). These assumptions have led to a lack of scientific attention on female genitalia (Langerhans et al. 2016). However, recent studies show that female genitalia also demonstrate a vast amount of variation. Although, in the past little was known about the rate of female genital evolution, a growing

volume of studies and literature suggests they have also rapidly evolved along with male genitalia. Ongoing research and novel methods are bringing forth new theories of selection responsible for the genital divergence in females, as well as possible patterns of coevolution of male-female genital evolution. To fully investigate both the causes and consequences of genital evolution we must consider the functions of both sexes and their interactions.

Definition

Genital mutilation involves permanent, physical modifications of varying invasiveness made to human sex organs that are performed for religious, cultural, social, or other reasons.

Introduction

Genital mutilation procedures are practiced on human males and females in different cultures across the world (Wilson 2008; World Health Organization [WHO], 2016). Both female genital mutilation (FGM) and male genital mutilation (MGM) encompass a diversity of surgical operations made to genitalia that vary in severity and could therefore involve the complete or partial surgical removal or modification of external genitalia (Wilson 2008; WHO 2010). Debates about FGM have often been framed using two well-intentioned positions that are typically at odds in principle: *cultural relativism*, and the similar doctrine of *ethical/moral relativism*, versus universal human rights (which according to the Universal Declaration of Human Rights include the right to life, liberty, the security of personhood, health, and education; Danial 2013). The philosophy of *cultural relativism* holds that moral values are valid to individuals of different societies, traditions, and groups and that we should show tolerance and respect for their customs (see Danial 2013). While debates about MGM (i.e., *circumcision*) also address human rights but less frequently involve the invocation of relativism, some scholars have argued that cultural bias is responsible for the normalization of ritual infant circumcision (e.g., Darby 2015; Solomon and Noll 2007). Consequently, different terminology is used to refer to genital mutilation for both males and females, often respective to the ethical position being advanced. Central to these debates is whether genital mutilation offers any benefits to the recipient – whether those benefits be social, cultural, physical, etc. – and whether they outweigh the risks of the procedure in question (e.g., see Danial 2013; Darby 2015). Although there is controversial, preliminary evidence suggesting that male circumcision may be

associated with a slight decrease in risk of acquiring the human immunodeficiency virus (HIV; e.g., Auvert et al. 2005), overall, no FGM procedures have been found to offer any medical benefits to its recipients (WHO 2016). Below, the practices of MGM and FGM are discussed in more detail, along with the nature of the controversies surrounding each.

Female Genital Mutilation

According to the WHO (2016), female genital mutilation refers to procedures that are deliberately carried out in order to alter or injure external female genitalia for nontherapeutic purposes. It is estimated that over three million girls are subjected to these procedures every year, with the girls between infancy and adolescence comprising the majority of the recipients (WHO 2016). These procedures take place most frequently in countries in Africa, the Middle East, and parts of Asia (WHO 2016). FGM also occurs in localities where it did not originate, such as North America, Australia, New Zealand, and Europe, due to emigration from countries where FGM is still commonly practiced (WHO 2010). Different surgical variations of FGM are performed that vary in severity and detrimental health consequences and are classified into four types: clitoridectomy (i.e., partial or total removal of the clitoris and/or the prepuce), excision (i.e., partial or total removal of the clitoris and the labia minora), infibulation, and other harmful procedures to the female genitalia for nonmedical purposes (e.g., piercing, scraping, cauterization; WHO 2010). The most dangerous form of FGM is infibulation, which involves surgically narrowing the vaginal orifice by slicing and sealing the labia minora and/or the labia majora together, and may or may not include the removal of the clitoris (WHO 2010). Numerous studies have documented both short-term and long-term health complications for recipients of FGM. FGM compromises women and girls' physical health, by creating immediate complications such as infection, extreme pain, hemorrhaging, and urine retention, as well as long-term problems, including cysts, infertility, difficulties with

childbirth, and recurrent infections, and can even result in death (WHO 2016).

There are several reasons for the practice of FGM in different cultures; however, many of them share the belief that such procedures signify femininity, purity, cleanliness, and chastity (Danial 2013; WHO 2016). FGM is often considered a rite of passage for women entering into adulthood, society, and marriage (Danial 2013; WHO 2016). In many of the cultures where FGM takes place, a woman's social status, viability for romantic relationships, economic security, and overall value are gravely diminished if she has not undergone these procedures, in large part because they are generally believed to establish that she is a virgin (Danial 2013). Thus, FGM is a socially upheld behavioral norm that is not intended to be harmful to the recipient, but nevertheless has serious consequences (WHO 2010).

Critics of FGM argue that these practices should be abolished for several reasons. Chief among them is the condemnation of FGM by opponents who maintain that none of the various procedures offer any direct benefits to those who undergo them and that, instead, they pose recipients undue psychological harm and health risks (WHO 2010, 2016). FGM is recognized by international organizations (e.g., the United Nations Children's Fund, the United Nations Populations Fund, the International Council of Nurses) to constitute an act of violence that causes extensive physical and psychosexual harm to women and girls (WHO 2010). Another charge by critics of FGM is that it violates the basic human rights of women and girls, including their right to health, life, information, freedom from violence, and physical integrity (WHO 2010). Some defenders of FGM invoke *ethical/moral relativism* (or the similar doctrine of *cultural relativism*) to justify the practices, although many do not necessarily condone FGM but hold an impartial position on the issue (see Danial 2013). Because the philosophy of *ethical/moral relativism* holds that there are no unbiased criteria for establishing what beliefs and practices are morally valid, and genital mutilation is practiced in a variety of forms, for diverse reasons, and in several different cultures, it is argued that these procedures reflect cultural

and religious norms (e.g., Shweder 2000). A common accusation made by critics of the anti-FGM movement is that they promote a Western imperialist narrative (e.g., Nnaemeka 2005; Shweder 2000). Indeed, *cultural relativism* arose in opposition to the historical tendency of prosperous Western nations to impose their ethical and cultural perspectives on less well-developed nations (Danial 2013). However well intentioned those who advance relativistic positions may be, there could be consequences resulting from the popularity of this perspective. For example, some health providers who do not themselves approve of FGM may agree to perform genital surgeries out of respect for sociocultural differences (WHO 2010). In opposition to the relativistic position on FGM, several global health organizations (e.g., Joint United Nations Programme on HIV/AIDS, UNICEF, WHO, International Federation of Gynecology and Obstetrics) contend that, while the freedom to practice religion and cultural traditions are secured by international law, individuals' fundamental rights trump their freedom to engage in surgical genital procedures on women and girls (WHO 2010).

Male Genital Mutilation

MGM is thought to occur in 25 % of societies worldwide, and as with FGM, it encompasses several surgical procedures that differ in severity and often represent a societal rite through which boys are granted social benefits (Wilson 2008). For example, the most pervasive MGM procedure, *circumcision*, refers to the removal of the penile foreskin (prepuce), whereas the most extreme, but less common, MGM procedure of *testicular ablation* is the practice of destroying or crushing one testis (Wilson 2008). Because infant circumcision is the most widespread form of MGM and elicits considerable controversy, it will be specifically discussed, below.

Routine male infant circumcision is a common procedure that the majority of newborn boys undergo in the United States, although it is not standard procedure in other industrial nations (Frisch et al. 2013). In the United States,

circumcision is an elective procedure that is performed at the behest of the infant's parents, who frequently cite religious, cultural, ethnic, or cosmetic reasons for deciding whether to circumcise their sons (Solomon and Noll 2007). Three recent studies found that circumcision may reduce the transmission of HIV in heterosexual men in geographic regions with outstanding HIV prevalence (e.g., Auvert et al. 2005), leading American medical associations, including the American Academy of Pediatrics and the Centers for Disease Control and Prevention, to endorse routine infant circumcision (Frisch et al. 2013). Critics have raised issues with medicalizing the procedure based on these findings, which they hold do not generalize to male infants, or homosexual men – who are at greatest risk for contracting HIV – since these studies used adult, heterosexual participants (e.g., Frisch et al. 2013). Instead, they argue that HIV is easily preventable by behavioral choices such as consistent condom use.

Critics of circumcision also contend that the alleged benefits of circumcision, if there are indeed any, do not outweigh the risks and/or potential risks resulting from the procedure (e.g., Darby 2015; Frisch et al. 2013; Solomon and Noll 2007). For example, circumcision may lead to complications ranging from minor problems, such as bleeding and meatal stenosis, to partial penile amputation (see Frisch et al. 2013). Although the extent of risks arising from circumcision is unknown, some work has shown that it may lead to reduced penile sensation and psychological and sexual issues (see Darby 2015; Frisch et al. 2013). Another criticism of ritual male infant circumcision comes from opponents who maintain that the procedure violates principles of bioethics, human rights, and the right to body integrity of minors who are affected (see Darby 2015).

Conclusion

Both FGM and MGM are procedures associated with alterations made to male and female genitalia that are most commonly performed on male infants (i.e., circumcision) and young girls

between infancy and adolescence (Solomon and Noll 2007; WHO 2016). Because children and infants are not generally considered to be capable of providing consent, genital surgeries performed on these vulnerable populations are deemed morally problematic by critics (see Darby 2015) and are argued to represent human rights violations (Frisch et al. 2013; WHO 2010). Some critics of circumcision have suggested that there is a double standard whereby male circumcision constitutes a harmful act that should be considered as legally and ethically objectionable as FGM (e.g., Darby 2015; Solomon and Noll 2007). Opponents of circumcision observe that MGM and FGM both involve risky and invasive operations made to normal, healthy genitalia in the absence of medical necessity and carry potential health and psychosexual consequences (e.g., infection, hemorrhaging, future sexual problems, regret of genital condition post-surgery; Frisch et al. 2013; Darby 2015).

Defenders of FGM frequently invoke *cultural relativism* and/or *moral/ethical relativism* to justify the surgical procedures. However, some advocates for male infant circumcision seem to appeal to culture, as well, to preserve its routine practice. These critics note that, while Western law views FGM as always impermissible (Solomon and Noll 2007), FGM in the form of a small incision may be less invasive than male circumcision, thus arguing that the United States are culturally biased in promoting male circumcision (Frisch et al. 2013; Solomon and Noll 2007). In this way, it is argued that MGM represents a normalized cultural tradition in the United States rather than a justifiable, medically necessary procedure, since scholars observe evidence for its medical benefits are scarce, inconclusive, and potentially absent (see Frisch et al. 2013; Solomon and Noll 2007).

Definition

According to the evolutionist perspective, altruism refers to behaviors that increase gains in fitness for the beneficiary (i.e., it favors the reproductive success and the maintenance of the species) at a certain cost to the benefactor. However, to better understand this psychological phenomenon, it makes sense to consider both proximal and distal causes. According to De Waal (2008), proximate causes refer to situations that promote psychological, neural, and physiological mechanisms of the organism, as well as behavior. Distal causes refer to the selective processes that maintain behaviors throughout the evolution of the species due to their consequences for fitness. In this sense, the author considers that to better understand the evolutionary causes of altruism,

one should focus on distal causes, particularly the effects of altruistic behaviors

Introduction

It is intriguing to contemplate how individuals of the human species, as well as others, can act so differently in the face of their fellow man in need, such that, at times, they ignore even desperate requests for help, while, at other times, they engage in actions that may endanger their own life, to try to help the other individual. Among a list of behaviors that are directed to benefit third parties, and considering their potentially high costs to the benefactor, altruistic actions are discussed in this entry.

The French philosopher Auguste Comte was the first to use the word altruism as a concept to oppose selfishness. The term refers to a notion that has become one of the most controversial themes in social and behavioral sciences, for it involves a discussion as to whether this psychological phenomenon is developed for selfish/extrinsic or genuine/intrinsic reasons. One might think that it would be a difficult term to define, since, on one hand, the literature recognizes altruism as an act aimed at benefiting another organism, yet on the other, there are conflicting views in discussion as to what factors would be involved in its costs and benefits. This is highlighted in the question of whether altruism is performed for intrinsic or extrinsic reasons (Bykov 2017), such as (respectively) satisfaction with life or gains derived from the action. However, considering the complexity and relevance of this construct, it is important to discuss the conception of altruism, with the desire to seek a better understanding and contribute to the discussion within this field of study. In view of this, we have presented at the beginning of the entry (definition session) what has been found in the literature with respect to genuine altruism.

In the literature, we find differing theoretical currents such as kinship selection or even reciprocal altruism directed toward understanding altruism. The perspective of altruism as arising from kin selection, in accordance with Lopreato

(1981), was developed by William D. Hamilton, in which altruistic actions develop taking into account genetic proximity to the beneficiary of the action. This approach thus argues that the probability of occurrence of altruism increases when the coefficient of relations between distributor and recipient increases and when the gains achieved by the beneficiary are greater than the costs to the benefactor. From the perspective of reciprocal altruism, elaborated by Robert L. Trivers, also as discussed by Lopreato, reciprocal altruism is developed in view of a high possibility of future repayment.

Considerable debates have been waged concerning kinship and reciprocal altruism. However, certain behaviors (such as those addressed to strangers in recognized need) have for some time been calling the attention of scholars. Such actions are often called pure, ascetic, or genuine altruism, the latter being the designation that will be adopted in this entry.

Genuine altruism is normally attributed to group selection (Lopreato 1981). In this sense, Boorman and Levitt (1980) argue that if certain genotypes multiply, reducing the possibility of extinction of a certain group, then phenotypes are likely to evolve, even if harmful to the individual. In accordance with this conception, groups possessing more altruistic individuals may well prevail over groups formed mostly by selfish subjects.

It seems that altruism may have been selected because of inclusive fitness. Particularly, in the case of the human species, people sometimes consider others within their social group as honorary relatives (Allen-Hermanson 2017), which ends up bringing advantages not only to the group but also to the individuals, since each of the individuals in the group enjoys an increased fitness as well. It should be mentioned that the concept of inclusive fitness was introduced by William D. Hamilton when discussing elevation of reproductive success probability, (a traditional conception of fitness developed by Darwin) as being alone insufficient to explain the plurality of behaviors that occur in nature in many species.

Altruism can be found in various species of the animal kingdom, such as insects, ants, and bees and even in human and nonhuman primates. Accordingly, research developed by De Waal

(2008) has confirmed that if newborn simians are rejected during weaning, their lives may be spared from possible consequences of the neglect if another member of the group takes over for their care, avoiding premature death.

With specific regard to human primates, Warneken and Tomasello (2009) argue that this would be a genuinely altruistic species, since aptitude for altruism arises at the beginning of ontogenesis, before socialization is able to exert an even greater influence on the baby's development. Consistent with this perspective, Warneken (2010) points out that the emergence of altruistic behaviors so early in ontogenesis suggests that social and moral norms are not the principal source of altruism. By contra-arguing that children grasp cultural patterns quickly and parents might be stimulating altruistic behaviors, the authors argue that if this was really the case, such altruistic manifestations would not be found in chimpanzees. Based on this set of ideas, in addition to environmental influences, it is proposed that altruism in the human species arises from a biological tendency, not predetermined as specific behavior, yet enabling a varied (and comforting) performance toward the subject who is in trouble (Warneken and Tomasello 2009).

The notion of genuine altruism involves three characteristics: (I) the helping act consists as an end in itself, not aiming at gains for oneself; (II) is practiced voluntarily; (III) is aimed at benefiting other individuals (Leeds 1963). From this logic, as truly altruistic behaviors/actions, we cite anonymous donations to charities, donation of food and clothing for victims of public calamities or natural disasters, or even donating hair for people with cancer. Certain considerations concerning genuine altruism have already been noted. However, for a better understanding of perspectives adopted toward this phenomenon, we believe that it is fundamental to address aspects questioning genuine altruism

Genuine Altruism: Points and Counterpoints

There are those who argue that altruism is developed in the light of future gains that such

actions might bring about, and it is then attributed to selfishness, albeit indirect. Nevertheless, Andreoni et al. (2017) have shown that even after suppressing incentives, in a considerable number of situations, research participants choose options that involve equal benefits for all involved and as well that avoid selfishness. Similarly, Forsythe et al. (1994) tested the hypothesis of justice, using dictator and ultimatum games in which the players receive an amount to divide between them. Contrary to expectations, the results, to a significant extent, indicated that players decided to donate to their opponent an amount equal to or greater than their own reward. This choice cannot be explained solely by some yearning for justice. The findings, at least in part, can be attributed to altruism.

The following question might be raised, “what would lead one individual to act for the other at the cost of his own fitness?” In order to try to understand this question, studies developed by one of the most notable theorists Daniel C. Batson discussing the dilemma of whether or not altruism can be purely attributed to selfish reasons become useful. Taking this paradox into account, and using as a starting point a defense of the conception of genuine altruism, he argues that altruism would be motivated by empathy, which culminated in the formulation of the empathy-altruism hypothesis. Additionally, this author in addition has developed experiments using selfish motivations in different situations, thus putting to the test the hypothesis and confirming it, as can be verified in Batson et al. (1981). From this perspective, empathy would be a proximal cause of altruism (De Waal 2008).

The conception that altruism may be motivated by empathy was not introduced recently, but it was proposed by Adam Smith and David Hume back in the eighteenth century. However, it was Batson who first formulated the *hypothesis of empathy-altruism*, which defends the idea that empathic emotional states foster the development of altruistic motivations and behaviors (see Batson et al. 1981).

In accordance with this hypothesis, an individual, upon verifying that someone is in need, experiences an empathic concern generated by observation, which, in turn, would lead to

behavior in response to the situation. And in this sense, the empathic concern presents itself as a propeller of the altruistic act directed toward the other, with the purpose of diminishing their suffering.

To illustrate this idea, the study by Batson et al. (1981) examined degrees of difficulty in escaping such situation without giving assistance (high or low) and of levels of empathy (high or low). University students were asked to observe a supposed student receiving electric shocks and had the option of assisting the person by receiving the shocks instead. The results demonstrated that high levels of empathy are accompanied by aiding activity, regardless of the cost (high or low) that such aid might require.

Along the same lines of thought, and in response to the conception that altruistic behaviors are based on potential rewards, Batson et al. (1983) argue that, if this were so, increases in pro-social actions would only occur in contexts in which people might think they are being evaluated, that is, in cases where their empathy is being measured before the development of pro-social acts. However, the literature indicates that participants perform acts of helping/altruism even before they realize that their levels of empathy are being evaluated.

Conclusion

Altruism is a controversial subject. Some scholars believe that behaviors aimed at benefiting another organism are developed for selfish reasons, such as a future reward. Others defend the idea that altruism is intended solely to assist another individual in a situation of recognized need. Given the existence of different perspectives on the origin of altruism, this entry purposes not to solve the theoretical conflicts but simply to briefly discuss genuine altruism.

This entry presents arguments that endorse altruism as motivated by intrinsic reasons, such as empathy. Thus, the studies of Batson, a recognized scholar involved in empirical studies and theoretical formulations regarding altruism, are emphasized. Although it is known that there is a hegemonic theoretical perspective that argues

that actions for the benefit of others are due to personal or species gains, more and more studies are being developed to understand genuine altruism. Indeed, the literature has been recognized that this psychological phenomenon has biological as well as environmental roots, enabling a behavioral repertoire as extensive as comforting for the individual in need (Warneken and Tomasello 2009).

Evolutionary psychology brings important contributions to understanding the roots of genuine altruism. However, any attempt to understand altruism on a solely phylogenetic basis, without taking into account factors such as ontogenesis, culture, and context, may be (given all of its complexity) too simplistic for human nature.

Definition

Using sexual selection to explain human psychology.

Introduction

The publication in 2000 of Geoffrey Miller's book *The Mating Mind: How Sexual Selection Shaped the Evolution of Human Nature* heralded the first in-depth and wide reaching exploration of how sexual, rather than natural, selection could explain human behavior and psychology (Miller 2000). A central premise of this book is that as human *encephalization* (brain growth) has been very rapid, lacks any obvious survival benefits, and is unique to one species, it cannot be adequately explained by theories drawn from natural selection. Instead, Miller (2000) believes that our mental traits can best be explained as being the result

of runaway sexual selection in order to signal desirable traits in mate choice.

The Mind as a Fitness Indicator?

Subsequently, Miller (2000) views the mind as a fitness indicator as it is an extremely effective way for an individual to signal their genetic quality. This is because as the complexity of traits increase, so too does the genetic input needed to allow the trait to develop. Similar to the peacock's tail, therefore, variability in the human brain will signal the *mutational load* (the number of genetic mutations present) of an individual, which can provide potential mates with a great deal of information about their genetic fitness.

Creativity

Based on the handicap principle, whereby an individual can advertize their true fitness only through signals that are costly to produce, Miller explores specific mental abilities. For example, he points to human creativity as an effective means of signaling mental fitness, and he uses human artistic output (such as art, music, and poetry) as examples of traits that have little or no role in survival but do in terms of reproductive success. Evidence of this can be seen in the higher number of sexual partners that professional and/or serious artists have compared to individuals who had no artistic output (Nettle and Clegg 2006). Furthermore, as signals of genetic fitness are expected to be greater in men due to asymmetry in parental investment, it has also been shown that men also become more creative when they have been romantically primed (Griskevicius et al. 2006) and creative men are preferred over richer men by fertile women (Haselton and Miller 2006).

Language Use and Vocabulary

Similarly Miller (2000) also examines language use through the lens of sexually selected signaling. Miller points out that although language use

overall has clear survival benefits, our vast vocabulary does not. Therefore he suggests that it is valuable in mate choice, as elaborate language use acts as an honest signal of genetic quality. Evidence of this can be seen in how high verbal proficiency increases attractiveness (Lange et al. 2014) and the finding that men use lower frequency (i.e., rarer) words following an encounter with a potential partner (Rosenberg and Tunney 2008).

Altruism as a Courtship Display

Miller (2000) also explores how altruism can be explained as being sexually selected. He agrees with other researchers who believe that altruistic behaviors can act as costly signals of quality and states it can be an important signal in human courtship. Building on this, Miller (2007) argues that, more widely, moral virtues (such as agreeableness, kindness, and heroism) can be sexually attractive and act as reliable signals of an individual's genetic and parenting/partner qualities. Subsequently a large body of research has provided evidence that such behaviors are indeed important signals in mate choice (e.g., Barclay 2010; Farrelly 2011).

Modern Day Consumerism as a Costly Signal

Finally, Miller (2009) extends his view of the importance of sexual signaling in human nature to modern-day consumerism. He argues that human instinct to display costly signals of quality combined with social norms has led to twenty-first century capitalism, include our fascination with expensive brands and modern technology (Miller 2009). Here he further suggests that our personality and general intelligence are also signaled through our choice of products and services, from brand of car to university degrees. As these traits can be appealing in mate choice at different levels (e.g., high agreeableness may be desirable for long-term relationships, whereas low agreeableness may be desirable for short-term), Miller

(2009) suggests that the vast range of things we can consume are the result of our motivation to signal to others our individual qualities.

Conclusion

Geoffrey Miller's contribution can be considered as pivotal in switching the emphasis in human sexual selection research from physical signals to mental and psychological ones. *The Mating Mind* (Miller 2000) offered a broad approach to this, but it was not without criticism. This includes a lack of supporting research at the time and issues with regards to whether female or mutual mate choice could be the driving force behind such adaptations. However, by viewing much of our nature as potentially the results of sexual selection, its influence extends to many of the key areas of research in evolutionary psychological science, such as altruism and language use.

Definition

Conspicuous consumption, a term first made popular by the American institutionalist economist Thorstein Veblen in his well-known book *The Theory of the Leisure Class* (1899), is the phenomena of the ostentatious display of high levels of wealth through the purchase and display of very expensive items (e.g., designer watches, fine wine, and sports cars) that usually offer few practical benefits above their basic equivalents but are exclusive to the very wealthy simply because of their very expensive price tags.

By this type of consumption of exclusive consumer products, the wealthy act to publicly display their accumulated wealth, and by this means they connote to their peers (and to others) that they have achieved very notable success in their working lives. Various additional meanings of conspicuous consumption have also been outlined, over and above the simple display function. Conspicuous consumption may also facilitate the

following: acting in conformity with conventional symbols; compensating for lack of sufficient symbols; compensating for lack of satisfaction; enjoying or instrumentally using goods; and making oneself more attractive to others (Wicklund and Vanderkerckhove 1999, pp. 106–110).

Introduction

This entry will first consider the origins of the conspicuous consumption concept in Thorstein Veblen's work, before proceeding to consider the more recent development of this concept by the evolutionary psychologist Geoffrey Miller. The first economist to use a variant of the term conspicuous consumption was actually John Rae in 1834, who wrote that: "Articles of which consumption is conspicuous, are incapable of gratifying the passion" (quoted in Stankovic 2008, p. 119). Therefore the concept of the public display of wealth was certainly discussed by economists and others before Veblen, although there was no precise term that was consistently applied to the phenomenon across all of the literature until Veblen coined the phrase "conspicuous consumption."

Veblen on Conspicuous Consumption

The economist who first made the concept of conspicuous consumption an important cornerstone of institutional economics, and thereby more widely known to the general public, was Thorstein Veblen in his book *The Theory of the Leisure Class*. It should be noted that there is an entire chapter devoted to conspicuous consumption in Veblen's book (Ch. IV), so only a brief account of some aspects of it can be discussed here. Here is Veblen on conspicuous consumption from 1899:

The quasi-peaceable gentleman of leisure, then, not only consumes of the staff of life beyond the minimum required for subsistence and physical efficiency, but his consumption also undergoes a specialisation as regards the quality of the goods consumed. He consumes freely and of the best, in

food, drink, narcotics, shelter, services, ornaments, apparel, weapons and accoutrements . . . Since the consumption of these more excellent goods is an evidence of wealth, it becomes honorific . . . Conspicuous consumption of valuable goods is a means of reputability to the gentleman of leisure (Veblen 1925 [1899], pp. 73–75).

Veblen explained further that as wealth accumulated significantly over time, the leisure class and its habits of conspicuous consumption differentiated into an elaborate system of hierarchical ranks and grades, including vicarious conspicuous consumption by wives and other dependents bearing the insignias of their wealthy masters. The larger the number of vicarious dependents that an individual was able to support, the greater was the connoted indication of their wealth.

Another important aspect of conspicuous consumption highlighted by Veblen was that: "Throughout the entire evolution of conspicuous consumption . . . runs the obvious implication that in order to effectually mend the consumer's good frame it must be an expenditure of superfluities" (Veblen 1925 [1899], p. 96). In other words, in order to be reputable expenditure, it must also be wasteful expenditure, or as Veblen termed it, conspicuous waste. However, he was at pains to clarify that a good "may be useful and wasteful both" and that even apparently purely ostentatious goods can also have some useful purposes as well (Ibid., p. 100). Conspicuous consumption eventually became Veblen's most well-known and widely employed concept and it quickly developed a productive life of its own outside the pages of *The Theory of the Leisure Class*.

Miller on Conspicuous Consumption

In his book *Spent: Sex, Evolution, and Consumer Behavior* (2009), Geoffrey Miller further developed and extended the conspicuous consumption concept in line with recent developments in evolutionary psychology and biology, and also behavior economics (Griskevicius et al. 2007). According to Miller:

People have radically diverse responses to the very idea of conspicuous consumption. Some folks

consider it blindingly obvious that most human economic behavior is driven by status seeking, social signalling, and sexual solicitation ... Other folks consider this an outrageously cynical view, and argue that most consumption is for individual pleasure ("utility") and family prosperity ("security") ... (Miller 2009, p. 106)
